Data source: [311]

The calculation of thermodynamic functions of hydrazine from spectroscopic data was the first thorough source of reliable data [313]. This work has been superseded by the JANNAF thermochemical tables, which present thermodynamic functions in 100-K intervals for liquid and gaseous hydrazine (Table 29). The JANNAF thermochemical tables are based on the critical evaluation of data from multiple sources.

**Table 29:** Thermodynamic functions of liquid and gaseous hydrazine.

| $T$<br>K      | $C_p^0$<br>J mol <sup>-1</sup> K <sup>-1</sup> | $S_0$   | $-(G_0 - H_0^{298})/T$ | $H_0 - H_0^{298}$<br>kJ/mol | $\Delta H_0^f$ | $\Delta G_0^f$ | $\log K_p$ |

#### 2.2.2.4 Enthalpy of Formation of Hydrazine Solutions

Enthalpy-concentration diagrams for a binary system can be prepared for fixed pressure, and to be complete, they should include data on the solid, liquid, and vapor phases. Such charts are useful for calculations involving heat balances with accompanying concentration changes, such as those that may occur in aqueous solutions of hydrazine [314].

#### 2.2.2.5 Computations of Enthalpy of Formation of Hydrazine

Computational methods for predicting enthalpies of formation based on the number of chemical bonds and the molecular structure usually yield data only for molecules in the gaseous state, and it is more difficult to obtain enthalpies of formation for the same molecules in condensed states.

The enthalpies of formation of  $N_2H$ , diazene (*cis*- and *trans*- $N_2H_2$ ),  $N_2H_3$ , and hydrazine  $N_2H_4$ , as well as their protonated species (diazonium,  $N_2H_3^+$  and hydrazinium  $N_2H_5^+$ ), have been calculated using a high-level electronic structure theory [315]. Energies were calculated using coupled cluster theory with a perturbative treatment of the triple excitations and employing augmented correlation consistent basis sets to perform a complete basis set extrapolation for the energy. Geometries were optimized with different basis sets. The enthalpies of formation at 0 and 298 K are listed in Table 31. In addition, the enthalpies of formation of  $CH_3NH_2$ ,  $CH_3NNH$ , and  $CH_3HNNHCH_3$  were calculated using isodesmic reactions.

The enthalpies of formation,  $\Delta H_f^{298}$ , of hydrazine, in both the gas and condensed phases, and the enthalpies of sublimation or vaporization have been estimated using quantum-chemical methods, and similar calculations were made for 36 hydrazine derivatives. The composite G4 method has been used along with isodesmic reaction schemes to derive a set of self-consistent, high-accuracy gas-phase enthalpies of formation [316]. To estimate the enthalpies of sublimation and vaporization with reasonable accuracy (5–20 kJ/mol), the method of molecular electrostatic potential (MEP) has been used. A value of  $\Delta H_f^{298}(H_2NNH_2, G) = 97.0 \pm 3.0$  kJ/mol was determined from 75 isogyric reactions involving about 50 reference species, where

**Table 31:** Predicted enthalpies of formation of gaseous hydronitrogen compounds at 0 and 298 K

| Compound                                    | Predicted |     |          |       | Measured |     |            |      |

Data source: [315]

for most of these species, the accurate  $\Delta H_f^{298}(\text{G})$  values were available in the Active Thermochemical Tables (ATcT) [317]. The calculated value was in excellent agreement with the reported results of the most accurate models based on coupled cluster theory (97.3 kJ/mol, the average of six calculations). However, the difference between the values predicted by high-level theoretical calculations and the experimental value of  $\Delta H_f^{298}(\text{H}_2\text{NNH}_2, \text{G}) = 95.55 \pm 0.19$  kJ/mol recommended in the ATcT and other comprehensive reference sources is quite large and requires further investigation.

In a subsequent examination of published experimental and computational predicted values for the enthalpy of formation of hydrazine vapor, the accuracy of the long-standing experimental enthalpy of formation of gas-phase hydrazine, fully confirmed in earlier versions of the ATcT, was reexamined in light of new high-end calculations of a different variety [318]. An overly optimistic determination of the vaporization enthalpy of hydrazine, which created an unrealistically strong connection between the gas-phase thermochemistry and the calorimetric results defining the thermochemistry of liquid hydrazine, was identified as the probable culprit of deviations. The new enthalpy of formation of gas-phase hydrazine, based on balancing all available knowledge, was determined to be  $111.57 \pm 0.47$  kJ/mol at 0 K ( $97.42 \pm 0.47$  kJ/mol at 298.15 K), which agreed with the ATcT data. ATcT version 1.11218 listed a  $\Delta H_f(0 \text{ K})$  of  $109.66 \pm 0.19$  kJ/mol;  $\Delta H_f(298.15 \text{ K}) = 95.51 \pm 0.19$  kJ/mol. The more recent ATcT version 1.118 value was only slightly different,  $\Delta H_f(0 \text{ K}) = 109.71 \pm 0.19$  kJ/mol; ( $\Delta H_f(298.15 \text{ K}) = 95.55 \pm 0.19$  kJ/mol). In both versions, the enthalpy is rather similar to the values listed in the NIST-JANAF tables ( $109.43 \pm 0.8$  kJ/mol at 0 K or  $95.35 \pm 0.8$  kJ/mol at 298.15 K).

### 2.2.3 Heat of Evaporation of Hydrazine

The literature offers a rather shaky choice of data for the enthalpy of vaporization (or latent heat of evaporation) of hydrazine. A striking observation is the lack of a genuinely experimental nature and reliability of the published data. They have all

been unconditionally estimated via approximate methods and accurate calorimetric determinations are lacking. Literature data for the enthalpy of vaporization were given only for one or, at most, two temperatures, far from the critical point. Data were all derived from the Clausius-Clapeyron equation and the slope of the vapor pressure curve, sometimes assuming ideal gas behavior for hydrazine vapor, which it certainly is not. A critical review of the rationale used by various investigators was performed by Giordano in 2001 [105]. It was emphasized that available vaporization-enthalpy data do not possess a sufficient degree of experimental purity. Their reliability could be undermined by overlooked inconsistencies and/or unverified inaccuracies.

The heat of vaporization is usually obtained from the slope of vapor pressure curves using the Clapeyron equation. Using Scott's [107] vapor pressure curve,  $(\Delta H)_{298}^{\text{vap}} \text{N}_2\text{H}_4 = 44.769 \pm 0.314 \text{ kJ/mol} = 10.700 \pm 0.075 \text{ kcal/mol}$  is obtained. Hieber and Woerner [206] calculated  $(\Delta H)_{296}^{\text{vap}} \text{N}_2\text{H}_4 = 42.68 \text{ kJ/mol} = 10.2 \text{ kcal/mol}$ . Hieber and Appel [319] measured a heat of vaporization at 273 K as  $48.1 \text{ kJ/mol} = 11.5 \text{ kcal/mol}$ . Using the combined vapor pressure curve given in Section 2.1.9.1, a value of  $(\Delta H)_{298}^{\text{vap}} = 43.43 \text{ kJ/mol} = 10.38 \text{ kcal/mol}$  is obtained. At the normal boiling point, the heat of vaporization is lower, only  $39.08 \text{ kJ/mol} = 9.34 \text{ kcal/mol}$ .

Trouton's rule states that the entropy of vaporization is almost the same value, about  $85$  to  $88 \text{ J K}^{-1} \text{ mol}^{-1}$ , for various kinds of non-associated liquids at their boiling points. The entropy of vaporization is defined as the ratio between the enthalpy of vaporization and the boiling temperature. The Trouton constant of hydrazine of  $24.1 \text{ cal mol}^{-1} \text{ }^\circ\text{C}^{-1}$  ( $100.8 \text{ J mol}^{-1} \text{ K}^{-1}$ ) is indicative of a strongly associated liquid. Audrieth [7] listed a Trouton constant of  $25.23 \text{ cal mol}^{-1} \text{ }^\circ\text{C}^{-1}$  ( $105.6 \text{ J mol}^{-1} \text{ K}^{-1}$ ), equally different from the value of  $21 \text{ cal mol}^{-1} \text{ }^\circ\text{C}^{-1}$  ( $87.9 \text{ J mol}^{-1} \text{ K}^{-1}$ ) expected for nonassociated liquids. A positive deviation from the theoretical value for nonassociated liquids is indicative of association in the liquid phase. This deviation is, of course, even more pronounced for water than for hydrazine (water:  $26 \text{ cal mol}^{-1} \text{ }^\circ\text{C}^{-1} = 109 \text{ J mol}^{-1} \text{ K}^{-1}$ ).

If one accepts the heat of evaporation at 298 K from Scott as  $10.7 \text{ kcal/mol}$ , the following equation can give the heat of evaporation as a function of temperature between 275 and 390 K. The original equation exactly as shown on page 74 of Audrieth and Ackerson-Ogg [7] is

$$\Delta H_{\text{vap}} = 15879 - 28.296T + 0.054525T^2 - 0.000068528T^3 \\ + 0.00000003125T^4 - 0.00000000008333T^5$$

where  $\Delta H_{\text{vap}}$  is the heat of evaporation in cal/mol and  $T$  is the temperature in kelvin. This equation can be converted to SI units, and then it reads

$$\Delta H_{\text{vap}} = 66438 - 118.39T + 0.228133T^2 - 2.8672 \times 10^{-4}T^3 \\ + 1.3075 \times 10^{-7}T^4 - 3.4865 \times 10^{-11}T^5$$

where  $\Delta H_{\text{vap}}$  is the heat of evaporation in J/mol and  $T$  is the temperature in kelvin. At the normal boiling point (386.6 K), which is outside the valid temperature range for this equation, this equation gives a heat of vaporization of 40.83 kJ/mol (9.758 kcal/mol).

### 2.2.3.1 Passivating Hydrazine Propellant Tanks in Outer Space

The heat of evaporation of hydrazine is the key parameter when constructing thermal models to predict the rate at which hydrazine propellant tanks empty themselves at the end of a mission when the propellant lines are opened to the vacuum of space to dump residual propellant. In the wake of some upper-stage (kick stage) explosive fragmentation events that created a cloud of orbital debris, mission planners now design spacecraft so that all residual hydrazine can be vented before the spacecraft reenters or overpressurizes when the hydrazine is locked up [320]. The PEGASUS Hydrazine Auxiliary Propulsion System (HAPS) fragmentation event demonstrated the importance of passivating spacecraft and upper stages at the end of missions by draining all propellant [321]. The sensible heat carried with room-temperature liquid-phase hydrazine isolated droplets in vacuum allows for the vaporization of a maximum of 30% of the liquid, with the rest remaining in the solid phase. The rate of sublimation of the cold hydrazine solid is much slower than the rate of evaporation of the liquid.

The thermodynamic properties of hydrazine, including the heat of evaporation, have been gathered in support of computations to predict how long it would take for a hydrazine propellant tank to empty and inert (passivate) itself to below the detonable partial pressure of hydrazine vapor. A numerical method (pressure-correction method using a staggered grid) was coupled to a thermodynamic model for compressible liquid hydrazine and applied to the venting of liquid hydrazine into space, during which the fluid underwent a large pressure drop [322–324]. Below the saturation pressure, vaporization occurs but insufficient energy is available for complete conversion to vapor. Some of the hydrazine will freeze and cause problems. Vaporization takes place near the outlet and induces variations of temperature, which may cause solidification and pipe clogging. To assess the risk of phase changes, numerical simulations of the venting line have been performed using a quasi-one-dimensional approach. The numerical method can handle compressible flows of fluids with nonconvex EOSs at the low Mach numbers that occur during hydrazine venting. A numerical study of the liquid behavior during sudden depressurization was performed for the tanks of the reaction control system of Ariane 5 upper stage, and the method was validated using experimental data and allowed for the prediction of the pressure profile and vaporization location along the pipe. It was deduced from these considerations that when one achieves the disposal of hydrazine reservoirs in vacuum after the operation of Ariane 5 upper-stage SCA, some risks of icing in piping exist, as well as obstruction of the exit orifice. The flow to be computed has a low Mach number:  $\text{Ma} < 0.03$ . Computations for an initial tank pressure of 25 bar indicated that liquid flashing occurred only near the outlet.

### 2.2.3.2 Flash Evaporation of Hydrazine in Vacuum

In addition to computer modeling, tank depressurization and passivating experiments have been conducted with simulated flight hardware in vacuum chambers on the ground, often using water as a surrogate liquid for hydrazine [325–328]. The shape and particle size of the hydrazine droplet-snow flake crystal spray emanating from the orifice sprayed into vacuum was studied with high-speed cinematography. It would have been of interest to examine whether this spray was associated with the buildup of static electricity.

The depressurization and emptying of a tank of liquid hydrazine once it is exposed to vacuum is aided by the effervescence of dissolved pressurant gas, like the opening of a champagne bottle. When hydrazine droplets are formed by flash evaporating liquid hydrazine into a vacuum and forming an aerosol, the sudden cooling does not allow crystals to order themselves, and the undercooled droplets consist of mixtures of disordered and crystalline phases [36]. Such clouds of hydrazine snow may exist on the planet Jupiter [35]. See also [329].

## 2.3 Molecular Structure of Hydrazine

The unique properties of hydrazines can be better understood by studying the nature of the chemical bonds that hold them together. The N–N bond is unique in being borderline between stable and labile. This provides for a wide range of possible reactions. Once individual bond energies are known, the enthalpies of formation of different molecules in the vapor state can be calculated by simply adding up the number of N–N, N–H, N–C, and C–H bonds in a molecule.

Many of the physical and thermodynamic properties summarized in the preceding chapter are closely interrelated with the molecular structure of hydrazine. Likewise, many molecular properties are related to the optical and electrical properties of hydrazines, which are discussed in subsequent sections of this chapter.

The peculiarity of hydrazine as a highly energetic compound has its origin in the molecular structure of this “dinitrogen tetrahydride.” The molecular structure, the bond strength, the bond length, and the geometric arrangement of hydrazine and some of its simpler derivatives thus deserve detailed discussion. One question that arises at this point is why the higher hydronitrogen homologues of hydrazine are so much less stable than hydrazine and why nitrogen is not capable of forming long-chain and ring compounds analogous to carbon compounds.

The molecular structure of hydrazine in its salts is slightly different from that of the parent molecule. Hydrazyl radicals are unique and partially responsible for the reactivity of hydrazine. The free radicals and intermediates in hydrazine decomposition are discussed in Section 4.4.2. One of the key parameters used in describing molecular structures is the bond length. Bond lengths are commonly measured in Ångstrom

units, which are not SI units. Nevertheless, for ease of conversion, the numerical values of molecular dimensions are reported in units of  $10^{-10}$  m, which is identical to 1 Å.

In an early quantum-mechanical study of hydrazine, it was theorized that the  $2s^2$  shell of the nitrogen atoms is not inactive in establishing a bond between the two nitrogen atoms, as one would first assume [330, 331]. Instead, a  $2s2p^3$  hybridization is assumed to occur that is like the tetrahedral arrangement in a saturated carbon atom and energetically favored. A pair of “lone” electrons with opposite spins occupies the place usually inhabited by a ligand in a carbon tetrahedron. Calculations showed that free rotation cannot occur in either of these molecules at ordinary temperatures and that the only stable forms are those in which the azimuth of one half of the molecule with respect to the other is twisted by approximately  $90^\circ$ . The essential feature of the argument is that the electrons of the two central atoms arrange themselves to form the strongest possible bonds and in so doing render the charge density on these atoms unsymmetrical about the axis of the molecule. The interaction of the two electronic clouds is the dominant factor in determining the azimuth of one group relative to the other.

In contradistinction to its organic analog, ethane, which can exist in only two conformations (eclipsed and staggered), hydrazine can theoretically exist in three conformations by rotating one half of the molecule around the N—N bond. As shown in Figure 33, a boat form, a chair form, and a totally unsymmetrical form can be drawn up for the  $N_2H_4$  molecule.

**Figure 33:** Possible hydrazine conformations

There are comparatively few compounds with the singly bonded  $>N-N<$  backbone because such systems are destabilized by the repulsion of the lone electron pairs on the two nitrogen atoms. The parent compound,  $HHN-NHH$ , is kinetically stable but thermodynamically unstable. The  $C_2$  symmetry *gauche* conformation of  $N_2H_4$  is known experimentally and theoretically to be the most stable structure. Rotation around the N—N bond as an axis leads to the less stable staggered (*anti*)  $C_{2h}$  conformer and an eclipsed (*syn*) structure. The latter conformation corresponds to a transition state, whereas the former is a local minimum on the energy potential surface.

### 2.3.1 Rotational Barriers in Hydrazine

Based on spectroscopic observations [217] and dipole measurements [332], the  $\text{NH}_2$  groups are not freely rotating around the N—N bond, but a rotational barrier of 25–41 kJ (6–10 kcal) must be overcome. This increase in energy leads to decomposition before spectra of the freely rotating molecule can be recorded. Instead of rotating freely, the two  $\text{NH}_2$  groups twist and oscillate against each other in the gas-phase molecule at room temperature. The rotational barrier compares to 10.7–13.8 kJ/mol (2.56–3.3 kcal/mol) for ethane; thus, the ethane rotation is “thawed” at room temperature and contributes to the specific heat of ethane gas. Dipole moment measurements of hydrazine (Section 2.8.2) also indicated that the molecule does not rotate freely [331]. Theoretical calculations based on three different variations of the molecular orbital theory have allowed prediction of the magnitude of rotational barriers [333]. The rotational barriers have been explained by the interaction of “lone-pair” orbitals of the lone electrons on neighboring nitrogen atoms.

If the two halves of the hydrazine molecule were rotating freely around the N—N axis, a tautomeric “amine-imide” form  $\text{H}_3\text{N}^+ - \text{NH}^-$  would be required to explain the dipole moment of hydrazine. However, this structure is highly unlikely.

The nuclear quadrupole coupling constants of the  $^{14}\text{N}$  nuclei for hydrazine were calculated by an *ab initio* SCF and by a CI calculation method. Rotational isomerism becomes evident as a form of energy state/line splitting in several spectra of hydrazine, including nuclear quadrupole coupling nuclear magnetic resonance (NMR) spectra [334] (Section 2.9) and electron spectroscopy for chemical analysis (ESCA), also called X-ray photoelectron spectroscopy (XPS), spectra (Section 2.6).

It was shown that an important consequence of nonrigid motions observed in the hydrazine molecule is the mixing of stereoisomers, although the geometrical symmetry group, taking into account these motions, similarly to the point group of one equilibrium configuration, has no improper transformations of the molecule as a whole [335, 336]. An important point is that the geometrical group of a nonrigid molecule is the so-called noninvariance dynamical group. The effect of mixing of stereoisomers on the total picture of nonrigid motions was considered using symmetry methods. It was shown that a nonrigid molecule exhibits properties of a symmetric top, whereas a rigid molecule represents an asymmetric top.

### 2.3.2 Bond Lengths and Bond Angles

Bond lengths and bond angles of the hydrazine molecule obtained by different authors using a variety of experimental methods and theoretical calculations are summarized in Table 32.

Besides the bond energy, the bond length and bond angles are also of interest to explain the behavior of hydrazine under certain conditions. These data are usually

**Table 32:** Bond lengths and bond angles of hydrazine.

| Bond  | Length ( $10^{-10}$ m) | Method | References |
|-------|------------------------|--------|------------|
| N—H   | 1.014                  | IR     | [337]      |
| N—H   | 1.022                  | IR     | [338]      |
| N—H   | 1.020 to 1.025         | IR     | [339]      |
| N—N   | 1.5                    | IR     | [337]      |
| N—N   | 1.449                  | IR     | [338]      |
| N—N   | 1.45                   | IR     | [340]      |
| N—N   | 1.46                   | X Ray  | [341]      |
| N—N   | $1.453 \pm 0.005$      | IR     | [339]      |
| Bond  | Angle (°)              | Method | References |
| N—N—H | 108                    | IR     | [337]      |
| N—N—H | 112                    | IR     | [338]      |
| N—N—H | 112 to 112.5           | IR     | [339]      |
| N—N—H | 112                    | IR     | [340]      |
| H—N—H | $105^{\circ}50'$       | IR     | [339]      |

derived from spectroscopic data. The following bond lengths were calculated for the ground-state molecule [337]:

$$\begin{aligned} \text{N—H} & 1.014 \times 10^{-10} \text{ m} \\ \text{N—N} & 1.500 \times 10^{-10} \text{ m} \end{aligned}$$

All bond angles are  $108 \pm 10^{\circ}$  as expected in a tetrahedral arrangement (theoretical angle  $109.5^{\circ}$ ). The following bond lengths and angle data were obtained from electron diffraction measurements:  $d(\text{N—N}) = (1.449 \pm 0.004) \times 10^{-10}$  m,  $d(\text{N—H}) = (1.022 \pm 0.006) \times 10^{-10}$  m, and bond angle  $\angle \text{NNH} = 112.0^{\circ}$  [338]. These results agreed well with IR data. Earlier IR spectra indicated an  $\angle \text{HNNH}$  angle of  $105^{\circ}50'$  [339]. The distance from the nitrogen to the nearest hydrogen belonging to a neighboring hydrazine molecule is  $(2.063 \pm 0.015) \times 10^{-10}$  m. There is active hydrogen bonding between the molecules.

### 2.3.3 Bond Energies of Hydrazine

The bond energy of individual linkages that hold the atoms together in a molecule determines the stability of the molecule and the amount of energy released when the molecule breaks apart. This process is what makes hydrazine a good monopropellant. Obviously, hydrazine is not a very stable molecule, and some explanation for this behavior is sought by studying the bond energies of hydrazine and its decomposition products. Bond energies can be derived from the natural frequency of atoms oscillating in the molecular skeleton by extrapolation of spectroscopic data, from ionization

and appearance potentials, or from calorimetric data. Bond energies are identical with dissociation energies required to break a particular bond (but there may be contributions by energy stored in other degrees of freedom of the molecule). Table 33 presents a summary of bond dissociation energy data in hydrazines. There is a wide scatter of dissociation energy data.

**Table 33:** Bond dissociation energies in hydrazines and ammonia.

| Bond                                     | Dissociation energy |          |          | References |
|------------------------------------------|---------------------|----------|----------|------------|
|                                          | kJ/mol              | kcal/mol | eV       |            |
| <i>Hydrazine and hydrazine fragments</i> |                     |          |          |            |
| H—N <sub>2</sub> H <sub>3</sub>          | 318 ± 21            | 76 ± 2   | 33 ± 2   | [342]      |

Many bond energy data were obtained as a valuable byproduct of mass spectrometric analysis of hydrazine and hydrazine derivative decomposition kinetics. When studying the decomposition products of hydrazine in a microwave-induced glow discharge, dissociation energies were derived from the appearance potential of NH<sub>2</sub><sup>+</sup>, N<sub>2</sub>H<sub>3</sub><sup>+</sup> in the mass spectrometer [342]. The bond dissociation energies were 443 ± 12 kJ/mol (106 ± 3 kcal/mol) for D(H—NH<sub>2</sub>) in ammonia, in good agreement with 435 ± 8 kJ/mol (104 ± 2 kcal/mol) reported earlier [354]. The dissociation energy of the N—N bond in hydrazine D(H<sub>2</sub>N—NH<sub>2</sub>) was calculated to be 318 ± 21 kJ/mol (58 ± 9 kcal/mol), in agreement with a previous, more precise, determination of 251 ± 12 kJ/mol (60 ± 3 kcal/mol) [351]. The dissociation energy required to form hydrazyl radicals was estimated to be D(H—N<sub>2</sub>H<sub>3</sub>) = 318 ± 21 kJ/mol (76 ± 5 kcal/mol), significantly below that for an N—H bond in ammonia.

Data for a dissociation energy  $D(\text{N}_2\text{H}_3-\text{H})$  of 481 kJ/mol (115 kcal/mol) [355] was rather high and was later revised. In a consecutive reevaluation of the accuracy of the use of appearance potentials or ionization potentials in mass spectrometers for determination of bond dissociation energies, the lower value,  $D(\text{N}_2\text{H}_3-\text{H}) = 326$  kJ/mol (78 kcal/mol), was later confirmed based on an independent empirical relationship by deriving the enthalpies of formation of nitrogenous free radicals from similarity laws [344, 345]. From the dissociation energies of isoelectronic molecules  $\text{CH}_3\text{CH}_2-\text{H}$  (406–410 kJ/mol = 97–98 kcal/mol) or  $\text{HOO}-\text{H}$  (372–376 kJ/mol = 89–90 kcal/mol), one would expect that the dissociation energy of  $\text{H}_2\text{NNH}-\text{H}$  is on the order of 372 to 410 kJ/mol or 89 to 98 kcal/mol.

The adiabatic ionization potential of  $\text{N}_2\text{H}_3$  was found to be  $7.61 \pm 0.01$  eV. This observation leads to  $D_0(\text{H}_2\text{NNH}-\text{H}) = 338 \pm 1.2$  kJ/mol =  $80.8 \pm 0.3$  kcal/mol, and  $D_0(\text{HN}=\text{NH}-\text{H}) \approx 183 \pm 4.6$  kJ/mol =  $43.8 \pm 1.1$  kcal/mol [356].

An *ab initio* study of the ionization potential of hydrazine calculated the equilibrium geometries and harmonic vibrational frequencies of the  $C_{2h}$  and  $D_{2h}$  conformers of the hydrazine ion ( $\text{N}_2\text{H}_4^+$ ) [357]. Extrapolation of the best results gave ionization potentials equal to 8.07 and 7.81 eV, which were close to experimental data, reported by others as  $8.1 \pm 0.15$  eV.

The dissociation energy of  $\text{N}_2\text{H}_3-\text{H}$  can be calculated from the difference of the appearance potential of the  $\text{N}_2\text{H}_3^+$  ion and the ionization potential of the  $\text{N}_2\text{H}_3$  radical:

$$D(\text{N}_2\text{H}_3-\text{H}) = A(\text{N}_2\text{H}_3^+) - I(\text{N}_2\text{H}_3)$$

This assumption is true only if  $A$  does not involve excess energy terms and if  $I$  is the adiabatic value, that is, corresponds to the 0–0 electronic transition. The equal sign should be replaced by a “less than or equal to”  $\leq$  sign if one wishes to be more accurate. Disregarding the effect of excess energy and adiabatic values may lead to the erroneous result initially obtained by Dibeler. An N–N bond energy of 251 kJ/mol (60 kcal/mol) and an N–H bond energy of 368 kJ/mol (88 kcal/mol) were assumed [348].

Nitrogen-hydrogen single-bond dissociation energies in hydrazine can also be estimated from the energy of activation in the abstraction of hydrogen atoms by methyl radicals [347]. These data favor a  $D(\text{H}-\text{N}_2\text{H}_3)$  on the order of 377 kJ/mol (90 kcal/mol), definitely weaker than the  $\text{H}-\text{NH}_2$  bond in ammonia.

It is very educational to compare the bond dissociation energy of N–H and N–N bonds in hydrazine to those in ammonia or molecular nitrogen. The bond dissociation energy of the N–H bond decreases with each consecutive hydrogen stripped off from ammonia, from 435 kJ/mol ( $104 \pm 2$  kcal/mol) in the first  $\text{H}_2\text{N}-\text{H}$  bond to 368 kJ/mol in the  $\text{HN}-\text{H}$  radical and finally 368 kJ/mol ( $88 \pm 6$  kcal/mol) in the  $\text{N}-\text{H}$  radical dissociation [354]. The same trend is observed with  $\text{CH}_4$ ,  $\text{H}_2\text{S}$ , or  $\text{H}_2\text{O}$ . The heats of formation for gas-phase species have also been calculated:  $\text{NH}_3$  –46.2 kJ/mol (–11.04 kcal/mol),  $\text{NH}_2$  +171 kJ/mol ( $+41 \pm 2$  kcal/mol), and  $\text{NH}$  +322 kJ/mol ( $+77 \pm 6$  kcal/mol). The corresponding values for radicals obtained by successive abstraction

of hydrogen from hydrazine have been determined beyond those for the hydrazyl radical [350]. These  $N_2H$  radicals would not be very stable because the N—N bond usually breaks before more than two hydrogens can be removed from hydrazine. The theoretical enthalpy of formation, heat capacity, and entropy of hydrazine vapor and a dozen other small molecule fragments was calculated using an isodesmic procedure [358, 359]. The calculated heat capacities and entropies agreed quite well with experimental data ( $C_p = 12.09$  calculated vs.  $12.20 \text{ cal mol}^{-1} \text{ K}^{-1}$  measured,  $S_0 = 55.46$  calculated vs.  $57.10 \text{ cal mol}^{-1} \text{ K}^{-1}$  measured).

The heat of dissociation of  $N_2$  has been a subject of considerable controversy for several years. It is very difficult to determine, because common spectroscopic methods fail as a result of the symmetry and lack of dipole moment of the molecule. Estimates for the N—N dissociation energy in  $N_2$  range from a low  $942 \text{ kJ/mol}$  ( $225.2 \text{ kcal/mol}$ ) to a high  $1138 \text{ kJ/mol}$  ( $272 \text{ kcal/mol}$ ). Because of this uncertainty, the heat of formation of NH cannot be calculated very accurately.

The N—N stretching force constants of diazene, hydrazine, and hydrazinium ions were calculated from spectroscopic data using a normal coordinate analysis and a modified valence force field method [360]. The N—N force constants in  $N_2H_2$ ,  $N_2H_4$ ,  $N_2H_5^+$ , and  $N_2H_6^{2+}$  were 10.22, 4.74, 4.80, and  $5.35 \text{ mdyn/\AA} = 1022, 474, 480$ , and  $535 \text{ N/m}$ , respectively.

### 2.3.4 Molecular Structure of Frozen Hydrazine

Frozen hydrazine may exist in the white clouds on Jupiter. The molecular structure in frozen hydrazine was measured by XRD [341]. The crystal structure of crystallized hydrazine is monoclinic  $C_{2h}^2 - P2_1/m$ , with two  $N_2H_4$  molecules in a unit cell of dimensions  $a = 3.56$ ,  $b = 5.78$ , and  $c = 4.53 \times 10^{-10} \text{ m}$ . The face angle is  $109.5^\circ$ . The N—N bond lies in the mirror plane, and the nitrogen atoms are  $1.46 \times 10^{-10} \text{ m}$  apart. The structure suggests the eclipsed configuration for the hydrazine molecule in the crystal, but hydrazinium salts assume a staggered configuration. Even if the hydrazine molecule has the eclipsed form in the crystal, there may be some reasonable doubt if this constellation survives if the molecule is vaporized. The spectroscopic data, at least until 1951, did not determine uniquely if the hydrogen atoms are in the opposed (*trans*) or eclipsed (*cis*) position.

Nuclear quadrupole relaxation spectroscopy of frozen hydrazine provided additional information about the lattice arrangement [361]. Six resonance lines due to two non-equivalent positions for each  $^{14}\text{N}$  nucleus in addition to the nonaxial symmetry of the crystalline field gradient, which gives rise to three resonance transitions were observed, and experiments of saturation recovery were carried out for these lines at liquid nitrogen temperature.

Numerous investigations attempted to resolve the question as to whether frozen hydrazine crystallizes in the  $C_{2h}^2 - P2_1$  space group or the  $C_{2h}^2$  space group. X-ray investigations first suggested a  $C_{2h}^2$  space group [341]. NMR [362–364] and far-IR [365] spectra

were shown to be consistent with a  $C_2^2 - P2_1$  structure instead. However, Raman spectra suggested another possible structure that is a monoclinic unit cell described by one of the  $C_{2h}$  space groups and containing four molecules located in general positions [366]. Only the positions of the nitrogen atoms have been established. More sophisticated proton spin-lattice relaxation measurements and some diffraction studies [367] now make the  $C_2^2$  space group more likely.

The molecular structure and molecular parameters of solid hydrazine are illustrated in Figure 34.

**Figure 34:** Molecular structure and molecular parameters of hydrazine molecule in solid state. (Reprinted and modified from [367], with permission from ©1975 Elsevier; permission conveyed through RightsLink)

It is surprising to learn that in frozen hydrazine between 200 and 260 K, the molecules have enough freedom of motion to exchange nitrogen nuclei between two nonequivalent crystallographic sites. This exchange has been detected by relaxation measurements of  $^{14}\text{N}$  nuclei by quadrupole NMR [368]. Line widths and spin-lattice relaxation times of the six nuclear quadrupole resonance lines of  $^{14}\text{N}$  in hydrazine were measured from 200 to 260 K using a pulse technique. It was shown that in this temperature range the dominant relaxation mechanism is a molecular motion that interchanges nuclei between the two nonequivalent crystallographic sites. The molecular motion has an activation energy of  $59.8 \pm 1.7 \text{ kJ/mol}$  ( $14.3 \pm 0.4 \text{ kcal/mol}$ ) and a rate of  $\sim 2500 \text{ s}^{-1}$  at 250 K.

The hydrazine monohydrate crystal is trigonal (space group  $P3_1$ ), with three molecules in a hexagonal unit cell.  $^{14}\text{N}$  NQR (nuclear quadrupole resonance) in hydrazine monohydrate has been investigated from 4.2 to 140 K [369]. A molecular motion with an activation energy of about 7.5 kcal/mol became active at about 120 K.

In frozen hydrazine hydrate, each hydrazine molecule is linked by six hydrogen bonds to the surrounding water molecules, and all nitrogen atoms in the unit cell occupy equivalent sites [370]. Each hydrazine molecule is separated from the nearest hydrazine molecule by six water molecules and allows a quasi-isolated two-spin system.

### 2.3.5 Computational Chemistry of Hydrazine Structures

Many chemists who never want to get their hands wet and have never taken a good whiff of hydrazine fumes have now resorted to computational modeling of hydrazine structures, working from the safe and convenient comfort of their offices. Ideally, these people should be able to design a new hydronitrogen rocket propellant and then give the blueprint to the lab chemists for further experimentation. Understanding the molecular structure of hydrazine helps to explain its reactive behavior in decomposition chambers in rocket engines. There are many different methods of modeling the molecular structure and predicting the physical properties of hydrazine and similar molecules [313, 371].

Anharmonic vibrational spectra of *gauche* conformers of hydrazine and hydrazine-d<sub>4</sub> were studied using vibrational self-consistent field and correlation-corrected vibrational self-consistent field methods within second-order Møller-Plesset perturbation theory [372]. Wavenumbers and intensities of both fundamental and overtone transitions were computed in different basis sets. Anharmonic spectra calculated on one potential energy surface were in much better agreement with experimental data than those obtained in another basis, but the energy sequence of  $\nu(\text{N-H})$  stretching modes was preserved in both basis sets. The wavenumber of the torsional mode was overestimated by 80 and 34  $\text{cm}^{-1}$  above its experimental position, respectively. The anharmonic spectrum of hydrazine-d<sub>4</sub> computed at the same level of theory also provided an adequate description of the experimental data, with the position of torsional vibration only 9  $\text{cm}^{-1}$  above the observed one.

Force field calculations for hydrazine were able to reproduce a range of equilibrium properties, including vapor-liquid coexistence densities, vapor pressures, enthalpies of vaporization, and critical properties [373]. Several dynamic properties, including self-diffusion coefficients and rotational time constants, were reported and found to be qualitatively consistent with experimental viscosities. Using this as a basis, a force field was also developed for the protonated form, i.e., hydrazinium-based cations.

#### 2.3.5.1 Calculations of Lone Electron Pair Interactions by Molecular Orbital Methods

The role of the two lone electron pairs on adjacent nitrogen atoms in preventing free rotation around the N—N bond has been investigated both experimentally through spectroscopic methods and computationally through molecular orbital and quantum-chemical methods.

It was once assumed that directional interactions of lone-pair orbitals make a significant contribution to the barrier energy [374], whereas others believed that lone pairs behave like ligands [375]. However, this would be in contradiction to the “rabbit-ear” effect of orbital interaction observed in hexahydropyrimidine. A single rotamer was predicted for  $\text{N}_2\text{H}_4$  at  $94^\circ$  with *cis* and *trans* barriers of 40.3 and 15.3 kJ/mol (9.64 and 3.67 kcal/mol) [376, 377].

Rotational barriers for hydrazine were calculated by an *ab initio* method and approximating complete neglect of differential overlap (CNDO) and intermediate neglect of differential overlap (INDO) methods. It was noted that the semi-empirical molecular orbital (MO) method results in barrier energies that are too low and in wrong torsional angles.

An attempt was made to explain the reasons for this discrepancy by recalculating the hydrazine molecule with the aid of the CNDO, INDO, and neglect of diatomic differential overlap (NDDO) methods, and an energy partition analysis was performed to account for the interaction of the lone electron pairs. [333]. The total energy and individual energy components were calculated and plotted as a function of the torsional angle. A minimum in the energy curve indicates the most stable position of the two  $\text{NH}_2$  groups in relation to each other. The difference between the peak and the valley gives the height of the rotational barrier. It was found that only the NDDO method made it possible to reproduce the results of the *ab initio* method and remain in agreement with experimental results.

Experimental results had indicated that the *gauche* form of hydrazine with a torsional angle of  $90^\circ$  is the most stable form [378]. The rotational barrier based on incomplete microwave studies was calculated to be approximately 13.14 kJ/mol (3.14 kcal/mol). The NDDO calculations by Wagner [376] and Koehler [333] gave 15.35 and 15.48 kJ/mol (3.67 and 3.70 kcal/mol) and  $94^\circ$  and  $\sim 100^\circ$ , respectively, in good agreement with each other.

Single Gaussian basis functions can represent lone-pair orbitals in contracted basis calculations. Using Pople's STO-4G and Dunning's *s-p* contracted basis sets, it was shown that optimum positions of lone-pair functions near the nitrogen nuclei are relatively insensitive to the molecular environment [379].

Improved bond-orbital calculations of rotation barriers in hydrazine and hydroxylamine using a STO-3G method looked at eleven different conformations of these molecules [380]. The results obtained using bond orbitals variationally optimized with respect to hybridization and polarity parameters showed that in the cases of lower local symmetry ( $\text{N}_2\text{H}_4$ ) second-order delocalization was essential for a correct description of the dependence of molecular energy on the dihedral angle.

Lone-pair interactions are also observed in other molecules like  $\text{HOOH}$ ,  $\text{H}_2\text{NOH}$ , or  $\text{H}_2\text{PPH}_2$ . For more information on conformational isomerism and force fields in the hydrazine molecule, see also [381–384]. Hydrazine is not a rigid rotor. Torsional wagging during rotation can lead to unexpected phenomena like tunneling of phonons [385, 386].

Others completely disregarded all references to previously published work and continued to calculate rotational barriers using a perturbation theory [340]. Lone-pair electrons associated to atoms located on the axis of rotation were effectively included in the model as additional nonbonded atoms. The researchers claimed that exchange interactions between the nonbonded atoms of the extended cluster were solely responsible for the observed conformation and rotation barriers. Their poten-

tial energy curve showed a minimum at  $\Theta = 75^\circ$  and a second less stable minimum at  $\Theta = 180^\circ$ . With respect to the equilibrium position, the *cis* and *trans* barriers were 25.15 and 10.5 kJ/mol (5.01 and 2.51 kcal/mol) high, respectively.

Other calculations for hydrazine and 10 hydrazine derivatives were performed using the intermediate retention of differential overlap (IRDO) MO method [387]. The repulsion of the lone pairs appears to be significant, favoring the form with perpendicular lone pairs over the *syn* and *anti* forms.

This agrees with gas electron-diffraction measurements [388]. Microwave measurements have also shown that hydrazine has a skew configuration with an equilibrium dihedral angle of  $90^\circ$  [389].

The modified intermediate neglect of differential overlap (MINDO/2) method was used to calculate conformations of hydrazine derivatives and compare them to results from XPS [390].

Molecular computational models for hydrazine, MMH, and UDMH molecules were derived to study the fluid phase behavior over a wide range of temperatures [239, 240, 391]. A parameterization of the classical molecular interaction models was carried out using quantum-chemical calculations and subsequent fitting to experimental vapor pressure and saturated liquid density data. To validate the molecular models, vapor/liquid equilibria for the pure hydrazines and binary hydrazine mixtures with water and ammonia were calculated and compared with available experimental data. The results for saturated densities, vapor pressure, and heat of vaporization obtained with this model were compared to the available experimental data and to the simulation results by Gutowski et al. Predicted critical point properties were  $T_c = 647.6$  K,  $p_c = 13.04$  MPa, and  $\rho_c = 10.16$  mol/L. In addition, the Henry's law constant for the physical solubility of argon, nitrogen, and carbon monoxide in liquid hydrazine, MMH, and UDMH was computed. In general, the simulation results were in very good agreement with the experimental data.

### 2.3.5.2 Calculations of Conformations and Lone Electron Pair Interactions by *ab initio* Methods

It has been pointed out that theoretical rotation barriers calculated for hydrazine by *ab initio* methods are probably too high [392]. The barrier to internal rotation in hydrazine has been calculated for values of 0, 60, 120, 180, and  $94^\circ$  (equilibrium conformation with energy minimum) of the dihedral angle, with all other bond angles and bond lengths fixed. The theoretical dihedral angle  $94^\circ$  was in good agreement with experimental indications of  $90$ – $95^\circ$ . The computed rotation barriers were 48.1 kJ/mol (11.5 kcal/mol) for the *cis* position and 20 kJ/mol (4.7 kcal/mol) for the *trans* position. Similar results were obtained using *ab initio* LCAO-MO-SCF wave functions [393]. Previously an energy minimum for  $\Theta = 90^\circ$ , a *cis* barrier of 46.23 kJ/mol (11.05 kcal/mol), and a *trans* barrier of 26.0 kJ/mol (6.21 kcal/mol) had been reported using an *ab initio* method [394].

Based on microwave spectra, a *gauche* conformation as the energy minimum ( $90^\circ < \theta < 95^\circ$ ), and assuming that both *cis* and *trans* barriers are equal, a barrier energy of 13.2 kJ/mol (3.15 kcal/mol) was predicted [378]. This did not agree too well with earlier results from other investigators [395, 396], who had used an *ab initio* restricted linear combination of atomic orbitals/molecular orbital/self-consistent field (LCAO-MO-SCF) method with bond functions. It was found that in its equilibrium conformation, the molecule had a dihedral angle of  $95^\circ$ . The barrier to pyramidal inversion at one nitrogen was 25.5 kJ/mol (6.1 kcal/mol) and the *syn* (eclipsed) and *anti* (staggered) rotational barriers were 50 kJ/mol (12.0 kcal/mol) and 6.7 kJ/mol (1.6 kcal/mol), respectively. The researchers' calculations indicated that during rotation over the *anti* barrier the bond angles contracted from their average equilibrium value of  $109.5\text{--}105.3^\circ$ .

A series of *ab initio* calculations was performed on hydrazine, 1,2-dimethylhydrazine, formamide, and its hydrogen-bonded dimer, 1,2-diformylhydrazine [397]. All systems were assumed to be planar. To study the changes in these bonds with variations in the ligands, the C—O, C—N, and N—N bond lengths were optimized in all cases. A systematic variation was found for the N—N bond when going from hydrazine via dimethylhydrazine to diformylhydrazine.

*Ab initio* SCF-MO calculations for  $\text{H}_2\text{NNH}_2$ ,  $\text{H}_2\text{NPH}_2$ , and  $\text{H}_2\text{PPH}_2$  showed that only the *gauche* conformation is a minimum energy level on the rotational curve of  $\text{H}_2\text{NNH}_2$  [398]. The pyramidal inversion barrier of hydrazine is slightly higher than that of ammonia.

Bond distances, bond angles, and total energies for the *gauche* and *anti* conformations of hydrazine in comparison to MMH were calculated using a modified Pulay's force method [399]. The predicted N—N distance of  $1.4509 \times 10^{-10}$  m of the *gauche* conformation is closer to the measured distance of  $1.45 \times 10^{-10}$  m than the value calculated for the *anti* conformation ( $1.5066 \times 10^{-10}$  m).

*Ab initio* calculations of the electronic spectrum and ionization potentials of hydrazine showed that all the first transitions appeared to belong to the first two Rydberg series, without any overlap with the valence transitions (which were expected to be above 11 eV) [400]. Comparing computer results to reported vacuum ultraviolet (VUV) spectra [401, 402] of hydrazine, the calculated splitting between the first two vertical ionization potentials is always lower than the experimental values. A rotation-torsion-inversion Hamiltonian function has been used to show that the inversion-torsion coupling in hydrazine is minimal and the inversion-inversion coupling is very strong [403, 404]. The barrier to inversion of  $2072\text{ cm}^{-1}$  is slightly higher than that in ammonia (which is a well-known microwave resonator). The barrier to an internal rotation of  $934\text{ cm}^{-1}$  calculated now is relatively high but lower than that reported by previous investigators using one-dimensional models.

Geometries, anharmonic vibrations, and torsion-wagging multiplets of hydrazine and its deuterated species were studied using high-level *ab initio* methods [405]. To describe the splitting patterns caused by tunneling in torsion-wagging states, the 3-D potential energy surface for the large-amplitude torsion-wagging modes was

constructed. The determined energy barriers, including the contributions from the small-amplitude vibrations, to the tunneling of the symmetric and anti-symmetric wagging mode of 1997 and  $3454\text{ cm}^{-1}$ , respectively, were in reasonable agreement with the empirical estimates.

*Ab initio* molecular orbital calculations and vibrational analysis confirmed that the *gauche* form with a dihedral angle close to  $90^\circ$  is the equilibrium conformation and that the *syn* form, which lies  $39.8\text{ kJ/mol}$  above the *gauche* form, is a transition conformation [406]. The energy level of the *anti* form, a weak equilibrium species, lies in a shallow minimum only  $7.7\text{ kJ/mol}$  above the *gauche* form. The *syn* form is only a transition structure for internal rotation, the barrier for which is  $36.9\text{ kJ/mol}$ . The barrier of inversion at one nitrogen atom is estimated to be somewhere around  $23\text{ kJ/mol}$ . Other *ab initio* calculations included the properties of molecular fragments of hydrazine and diazene (diimine) [407]. In discussing molecular structure and rotational barriers in hydrazine, its behavior has been repeatedly compared to that of its electron analogs hydrogen peroxide [379, 408, 409] and hydroxylamine, and MO/*ab initio* calculations were performed for all these molecules [410].

Equilibrium geometries and harmonic vibrational frequencies of the  $C_{2h}$  and  $D_{2h}$  conformers of the hydrazine ion  $\text{N}_2\text{H}_4^+$  were calculated using an *ab initio* method [357]. Valence and all electron correlation calculations were carried out using the correlation-consistent core and valence polarization triple-zeta basis set. The adiabatic ionization potential of hydrazine was calculated using two different methods, and the best predictions were  $8.07$  and  $7.81\text{ eV}$ , which were close to the experimental data, measured as  $8.1 \pm 0.15\text{ eV}$ .

The structural and spectroscopic properties of hydrazine were investigated by means of *ab initio* molecular dynamics, *ab initio* path integral molecular dynamics, and *ab initio* ring polymer molecular dynamics simulations in conjunction with electronic structure calculations [411]. Whereas the former method relies on the classical approximation of nuclear motion, quantum effects on structure and dynamics were considered at finite temperatures by *ab initio* path integral and *ab initio* ring polymer molecular dynamics, respectively. It was shown that quantum-mechanical fluctuation effects of the nuclei, in addition to their purely thermal activation, cause significant configurational fluctuations due to strongly anharmonic vibrations and, thus, increase the explored regions on the Born-Oppenheimer potential energy surface at room temperature. Including these effects, in turn, leads to significant improvements in the computed spectra compared to stick spectra obtained at the equilibrium structure by means of harmonic normal-mode analysis, as well as by classical *ab initio* molecular dynamics.

Optimized equilibrium geometries, harmonic frequencies, and rotational constants of the *gauche* conformer ( $C_2$  symmetry) of hydrazine were calculated employing a large series of basis sets and several *ab initio* methods [412]. The computed equilibrium geometries of the molecular structure were  $r_{\text{NN}} = 1.434\text{ \AA}$ ,  $r_{\text{NH}_1} = 1.013\text{ \AA}$ ,  $r_{\text{NH}_0} = 1.010\text{ \AA}$ ,  $\angle\text{NNH}_1 = 111.3^\circ$ ,  $\angle\text{NNH}_0 = 106.8^\circ$ , and  $\angle\text{H}_1\text{NNH}_0 = 89.7^\circ$ .

### 2.3.5.3 Dipole Moment Predictions of Hydrazine Molecule

Comparison of dipole moment measurements with INDO-calculated dipole moments for hydrazine vapor between 10 and 1000 K showed good agreement [413]. Calculations of free electron pairs in localized CNDO/2 wave functions of nitrogen compounds for hydrazine gave information on the type of hybridization of nitrogen “lone-pair” orbitals and free electron pair interactions in various N—N compounds [414].

Quantum Monte Carlo (QMC) calculations of the electric dipole moment and ground-state total energy of hydrazine used two QMC techniques: variational Monte Carlo (VMC) and diffusion Monte Carlo (DMC) techniques [415–417]. The electric dipole moment of the  $\text{N}_2\text{H}_4$  molecule was calculated using only the DMC technique. This gave an electric dipole moment value of 2.0 D, which was in good agreement with the experimental value of 1.85 D. Similarly, the ground-state total energy of the  $\text{N}_2\text{H}_4$  molecule was calculated using both VMC and DMC methods.

### 2.3.5.4 Computational Chemistry of Hydrazine Decomposition

Most theoretical CNDO, SCF-MO, LCAO-MO, MINDO, and other calculations discussed earlier are concerned with only the intact, vibrating, and rotating molecule of hydrazine. They will eventually indicate the limit of stability where the molecule will begin to break apart. Other calculations have taken the CNDO/INDO technique one step further and calculated potential energy surfaces for N—N bond rupture in hydrazine [418]. The calculation results agree with experimental data that indicate that amino radical recombinations occur without activation energies. Two amino radicals approaching each other do not have to overcome energy potential barriers in the approach as long as the two  $\text{NH}_2$  are oriented such that the  $\text{NH}_2$  flap angles with respect to the line joining the two nitrogen atoms are more than  $20\text{--}30^\circ$ . Computationally, the easiest pathway for photodecomposition of  $\text{N}_2\text{H}_4$  is through N—H rather than N—N bond rupture (in agreement with experimental results). In a different mathematical exercise, the results obtained with 62122 mixed basis sets were closer to the experimental values of the  $\text{N}_2\text{H}_4$  molecule than those obtained with standard basis sets as the single configuration level [419].

The decomposition of hydrazine ions in the beam of a mass spectrometer leads to different fragments. The unimolecular chemistry of  $\text{NH}_2\text{NH}_3^+$  formation and decomposition has been investigated experimentally and theoretically [420]. In accordance with experiments, losses of  $\text{H}_2$  and  $\text{H}^\bullet$  were calculated to be the dominant low-energy processes. A weak signal due to loss of  $\text{NH}$  with the formation of  $\text{NH}_4^+$  was also observed. The reaction dynamics of the  $\text{H}_2$  loss was investigated in great detail. This process has a substantial reverse barrier and a large non-statistical translational energy release. An *ab initio* direct dynamics calculation provided some insight into the process and was in agreement with the experimentally determined translational energy release. The proton affinity of  $\text{H}_2\text{NNH}_2$  was calculated and found to agree with experimental numbers.

### 2.3.5.5 Computational Chemistry of Hydrazine Cluster Formation, Hydration, Association, and Dissociation

Much of the interaction between hydrazine molecules and their surroundings is influenced by hydrogen bonding. Hydrazine would boil at a lower temperature close to that of its structural analog ethane if it did not have intermolecular hydrogen bonds. The diffusion properties and hydration structure of hydrazine in an aqueous solution were investigated through molecular dynamics simulations and split-flow pulse injection diffusion experiments [421]. The simulations were performed based on ambient conditions along the liquid side of the liquid-vapor coexistence curve, up to the critical point, and in the supercritical region at temperatures of 673, 773, 873, and 973 K and at densities ranging from 0.1 to 0.8 g/cm<sup>3</sup>. Such conditions may exist in steam power plants. The spatial distribution functions for hydrated water were derived. Under ambient conditions, hydrazine is hydrated by 24 water molecules with about 1.6 H-bonds being donated to each nitrogen atom. The hydration number decreases with temperature along the coexistence curve and is seen to increase with system density in the supercritical region. Under low-density supercritical conditions, hydrazine has no appreciable hydration structure and is surrounded by only two water molecules at 873 K and 0.1 g/cm<sup>3</sup>. The diffusion coefficients for hydrazine at subcritical state conditions agreed with Stokes-Einstein and Wilke-Chang predictions. The diffusion coefficients in the supercritical region were found to correlate more closely with the overall fit to the Dymond equation.

### 2.3.6 Isohydrazine and Ylide Structures

Besides resonance structures for hydrazine and its derivatives, in which electrons occupy different places in the molecule, tautomeric unsymmetrical ylide forms have been proposed, in which the hydrogen atoms are no longer equivalent if they are attached to two different atoms. Tautomeric amide-imide forms (“iminoammonium”) have been drawn up by theoretical chemists, but never proven to exist for hydrazine itself:

Tautomerism of this kind may play a role in intramolecular rearrangements found with aromatic hydrazine derivatives, but not hydrazine itself. Using the STO-3G method, bond lengths and angles for the hypothetical isohydrazine have been calculated: N<sup>1</sup>—H 1.037 × 10<sup>-10</sup> m, N<sup>1</sup>—N<sup>2</sup> 1.643 × 10<sup>-10</sup> m, N<sup>2</sup>—H 1.069 × 10<sup>-10</sup> m, angle ∠HN<sup>1</sup>H 106.5°, angle ∠N<sup>1</sup>N<sup>2</sup>H 94.0° [422, 423]. It has been pointed out that the isohydrazine molecule is isoelectronic with methanol, an otherwise very stable molecule. However, in isohydrazine the axis of the H<sub>3</sub>N pyramid is not in line with the N—N bond. The two axes are inclined against each other by 5.6°. Another set of

*ab initio* calculations concluded that isohydrazine, once formed, would be relatively stable since the barriers for its unimolecular isomerization and decomposition are relatively high [424]. But HNNH<sub>3</sub> is unlikely to be isolated in measurable amounts since bimolecular tautomerization takes place very rapidly. It should at least be considered an intermediate in hydrazine reactions.

The possibility of electron binding to the HNNH<sub>3</sub> or H<sub>2</sub>NNH<sub>2</sub> tautomers of hydrazine was examined at the coupled cluster level of theory with single, double, and noniterative triple excitations in an *ab initio* study [425]. The HNNH<sub>3</sub> tautomer, with a dipole moment of 5.4 D, binds an electron by 1076 cm<sup>-1</sup>, whereas the H<sub>2</sub>NNH<sub>2</sub> tautomer forms neither a dipole- nor valence-bound anionic state. A valence-bound anionic state for either the *gauche* or staggered conformations of H<sub>2</sub>NNH<sub>2</sub> or for HNNH<sub>3</sub> was not found. The dipole moment of 2.0 D for the *gauche* structure is too small to substantially bind an excess electron. The results indicate that the HNNH<sub>3</sub> tautomer of hydrazine can bind an electron, whereas the well-known H<sub>2</sub>NNH<sub>2</sub> tautomer cannot. This suggests a possible practical route to the formation of the HNNH<sub>3</sub> tautomer through photodetachment of an excess electron from N<sub>2</sub>H<sub>4</sub><sup>-</sup>. The neutral and anionic HNNH<sub>3</sub> are predicted to be kinetically stable with respect to tautomerization (having barriers of 98.7 and 107 kJ/mol, respectively), though thermodynamically unstable by 182 and 169 kJ/mol (with respect to the neutral H<sub>2</sub>NNH<sub>2</sub>), respectively.

Recombination of two amidogen radicals, NH<sub>2</sub> + NH<sub>2</sub> → N<sub>2</sub>H<sub>4</sub>, is relevant to hydrazine formation, ammonia oxidation and pyrolysis, nitrogen reduction (fixation), and a variety of other N/H/X combustion, environmental, and interstellar processes [426]. A comprehensive analysis of the N<sub>2</sub>H<sub>4</sub> potential energy surface, using a variety of theoretical methods, with thermochemical kinetic analysis and master equation simulations used to treat branching to different product sets in the chemically activated NH<sub>2</sub> + NH<sub>2</sub> process showed that iminoammonium ylide (NH<sub>3</sub>NH), the less stable isomer of hydrazine, may be involved in the multitude of N<sub>2</sub>H<sub>4</sub> formation and decomposition reactions. A termolecular reaction is an entropically disfavored path, but it does describe a new means of nitrogen fixation by activating the notoriously unreactive N<sub>2</sub>.

### 2.3.7 Molecular Structures of Other Hydronitrogens

The molecular structures of other hydronitrogens, such as diazene (“diimine”), triazane, tetrazene, hydrogen azide, hydrazinium cations, and hydrazine-derived free radicals, have been studied by computational chemistry because these compounds are either short-lived intermediates in the decomposition of hydrazine or were considered building blocks for other, more energetic hydrogens. A summary of the molecular structures of these entities is given in [427] and in *Encyclopedia of Liquid Fuels*, chapter “Hydronitrogens.”

## 2.4 Optical Properties of Hydrazine

This section deals with the interaction of hydrazines with electromagnetic radiation in a wavelength range of 100 nm to 20 cm. Correspondingly, the section is subdivided into UV absorption, IR absorption, and microwave absorption. The spectra obtained in these spectral ranges are of interest in the clarification of the molecular structure of hydrazine and measurement of the energies of the atomic/molecular bonds in it. Since the hydrazine N—N bond (as opposed to the azo bond N=N and its many azo dyes) is not a chromophore, there is nothing to report on the light absorption of hydrazine derivatives in the visible range. Practical applications of hydrazine spectra are in the analytical methods for measuring hydrazine concentrations in water or in air and for tracking the environmental fate of hydrazine that has been released into the atmosphere but is quickly destroyed by light and autoxidation.

The only spectra recorded for hydrazine are absorption and fluorescence spectra. The molecule is so unstable that it decomposes prior to the emission of characteristic molecular emission spectra when excited in an electric glow discharge. However, hydrazine as a lasing medium is a new research area and offers additional insight into the nature of the molecule. The emission spectra of fragments have been observed and are discussed in the following section.

### 2.4.1 UV Absorption Spectra of Hydrazine

It is very difficult to measure the UV spectra of hydrazine because the same radiation required to analyze the sample will also cause photolytic decomposition. In most cases, the UV spectra of hydrazine are intermixed with those of decomposition products. Reference to the UV absorption spectra is made in Section 4.6.2 on the UV photolysis of hydrazine. Once the absorption spectra of the decomposition products are subtracted, the absorption of the parent molecule can be mathematically derived.

The UV spectrum of hydrazine vapor consists of five or six nearly equidistant absorption maxima at about 232.6, 232, 227.6, 225, and 222.5 nm, followed by a continuous absorption below 220 nm extending all the way into the quartz-UV region [428, 429]. No rotation structures can be seen in the band absorptions at 5.4 Å per mm dispersion. Extending these measurements to shorter wavelengths, vacuum UV spectra of hydrazine vapor at up to 0.9 mbar were recorded in a 20-cm cell with a LiF entrance window and a quartz exit window [430, 431]. The absorption increased from 200 to 105 nm with two peaks at 190 and 170 nm, a weak peak at 153 nm, and a barely visible shoulder around 200 nm. Hydrazine vapor flowed through the cell at such a rate that photolysis decomposition products could not accumulate in the cell. An attempt was made to correlate the peaks with transitions predicted by the coupled electron pair approximation method [432]. Absorption at 165 to 210 nm was predicted to be dissociative. Although it has been observed that hydrazine mainly photodissociates to  $\text{N}_2\text{H}_3^\bullet$  and  $\text{H}^\bullet$  with a quantum yield near unity, emissions from fragments like excited

NH or  $\text{NH}_2$  may interfere with the hydrazine spectra. Complete knowledge of the UV spectra of the  $\text{NH}_2$  radical is needed to understand the spectra of hydrazine decomposition intermediates and products. Such information can be obtained by laser absorption spectrometry [433, 434]. Since the bond energy of N—D bonds differs from that of N—H bonds, UV spectra of deuterated hydrazine would result in absorption at different wavelengths [435]. Vacuum UV absorption coefficients for hydrazine, MMH, and UDMH were measured from 115 to 185 nm to determine interference with UV sensors in space applications [436]. Similar measurements of UV absorption cross sections at 191 to 291 nm determined the hydrogen atom quantum yield at 248 nm [437]. For the UV absorption of  $\text{N}_2\text{H}_4$  at 213.9 nm a UV absorption cross section of  $\sigma = 220.5 \times 10^{-20} \text{ cm}^2/\text{mol}$  was assumed for hydrazine photolysis and autoxidation studies in the atmosphere.

Vacuum UV absorption coefficients for hydrazine, MMH, and UDMH were measured from 115 to 185 nm to determine interference of leaked propellants with UV sensors in space applications [436]. Vacuum UV absorption coefficients for  $\text{N}_2\text{H}_4$ ,  $\text{CH}_3\text{HNNH}_2$ , and  $(\text{CH}_3)_2\text{NNH}_2$  were measured for wavelengths between 115 and 185 nm with an estimated experimental error of  $\pm 15\%$ . The measurements were made in a hydrazine-compatible flow-cell apparatus at room temperature.

Whereas ammonia has a distinct band structure of absorption bands between 120 and 200 nm, hydrazine essentially shows a continuum absorption in this range without much structure [438]. Measurements were made at a pressure of 0.8 to 1.5 mm Hg, and a flow of hydrazine was passed through the absorption cell to purge out photolysis products. A hydrogen lamp served as light source; it emits a continuum down to 165 nm and a mix of continuum and line or band structures between 165 and 120 nm. The VUV spectrum of hydrazine vapor showed three poorly defined shoulders at 218, 178, and 155 nm [401, 402]. The band shapes can be attributed to planarization of the Rydberg states. When the  $C_2$  pyramidal *gauche* geometry of the neutral molecule changes to  $D_{2h}$  planar geometry after losing a proton and becoming an ion, structural relaxation energies allow many energy states and wash out the sharp edge of photolysis threshold. The determination of absorption spectra of hydrazines in the vacuum UV region is complicated by premature photolysis.

A frequently observed intermediate in hydrazine decomposition or oxidation reactions is diazene (“diimine”)  $\text{HN}=\text{NH}$ . It has a distinct UV absorption spectrum with  $\lambda_{\text{max}}$  near 400 nm [439–441].

#### 2.4.2 IR Absorption Spectra of Hydrazine

IR spectra of hydrazine are extremely useful in identifying contaminants or verifying the absence of contaminants. Such spectra give information on the molecular structure of the  $\text{N}_2\text{H}_4$  molecule and allow the calculation of thermodynamic properties. It is common practice to describe spectra by giving wave numbers and intensities of absorption bands. The following abbreviations are in use for peak heights: **vs**, very

strong; **s**, strong; and **w**, weak. Wave numbers (in  $\text{cm}^{-1}$ ) can be converted to wavelength (in  $\mu\text{m}$ ) by forming the reciprocal

$$\lambda = \frac{10000}{\nu}$$

A common unit for wave numbers is reciprocal centimeters,  $\text{cm}^{-1}$  = kayser. This gives the number of wavelengths that fit into 1 cm. A chapter on IR spectroscopy could also be subdivided by the experimental technique used, of which there are quite a few: transmission, reflectance, attenuated total reflectance, vapor absorption, liquid absorption, mulls, emulsions, solid films, solid matrix isolation, adsorbed state on solid surfaces, complexed state in ligand spheres, isotope substitution, Fourier transform enhanced, and many more. Almost all of these methods have been applied to measure the IR spectra of hydrazine and hydrazine derivatives at one time or another. The following sections are subdivided by the physical state of the hydrazine for which IR spectra are being reported. Raman spectroscopy and IR spectroscopy complement each other, so there is some overlap.

IR spectra of hydrazine have been reported and interpreted in numerous publications, including [217, 442]. It would be difficult to provide a listing of all the IR spectra handbooks that include hydrazine. With the recent advent of online databases on the Internet (a few of these available for free), IR spectra and other physical data are now becoming available to computer users with the click of a mouse. This is the easiest way to obtain the most recent spectra in digital form.

Early efforts to assign frequencies and determine the symmetry of the hydrazine molecule were hampered by the lack of data for the corresponding deuterated molecule. All that could be said at that time based on a comparison of calculated (calculated for  $\theta = 0, 60, 90, 120$ , or  $180^\circ$  rotational distortion) and measured IR data was that the most likely angle of rotation from one  $\text{NH}_2$  group to the next was  $\theta = 90^\circ$ , which speaks for a *gauche* conformation of the molecule [443]. An initial summary of frequency assignments for hydrazine  $\text{N}_2\text{H}_4$  in the solid, liquid, and gaseous state is shown in Table 34, based on data from [313, 444–447].

The IR spectra of tetradeuterated hydrazine in the solid, liquid, and gaseous state were measured from 250 to  $4000\text{ cm}^{-1}$ , which allowed more specific assignments of absorption bands. To present a complete set of data, the Raman spectra of liquid  $\text{N}_2\text{H}_4$  and  $\text{N}_2\text{D}_4$  were also measured and included in the discussion and frequency assignments, as shown in Table 35.

For researchers studying molecular vibrations and their relations to absorption spectra, also applying quantum-mechanical computations for the molecular structures, the hydrazine  $\text{H}_2\text{NNH}_2$  molecule offers more of a challenge than comparable, simpler molecules like  $\text{HO}-\text{OH}$  or  $\text{H}_3\text{C}-\text{CH}_3$ . Molecular orbital calculations were aimed at interpreting the first excited state of the anti-symmetric wagging vibration [451], the R branch of the anti-symmetric wagging vibration at  $1002$  to  $1006\text{ cm}^{-1}$  [452], and a torsional-wagging tunneling problem in hydrazine vapor [385].

**Table 34:** Vibrational spectra data of hydrazine.

| IR                 |                     |                    | IR spectra of matrix<br>[447] |                  | Raman spec-<br>tra of liquid<br>[313] | Vibration and<br>symmetry type<br>assignments |            | Refer-<br>ences,<br>assign-<br>ments |

Compiled from multiple data sources

Every line of the R branch splits into four components. Explicit expressions for torsional-wagging rotational Hamiltonian matrix elements, also in comparison to hydrazine-like molecules, and a Fourier transform spectrum of the second torsional band of hydrazine were given by [453, 454]. Torsional-wagging-rotational matrix elements for the three large-amplitude vibrational and rotational problem in hydrazine were derived in a more convenient form and in more detail using a separate treatment of the large-amplitude vibration and the overall rotation [386]. Torsional-wagging-rotational basis set functions were defined for each symmetry species of the permutation-inversion group  $G_{16}$ , and  $\Delta K = 0, \pm 1, \pm 2$ , and  $\pm 4$  Hamiltonian matrix elements constructed from these basis sets were given in terms of tunneling parameters, which can be used directly in a least-squares fitting procedure of spectra of hydrazine-like molecules.

The Fourier transform spectrum of the anti-symmetric amino-wagging band of hydrazine has been reanalyzed [455]. About 1700 transitions from 18 sub-bands with  $K'$  from 0 to 6 were newly assigned. In place of a global fit, which proved unsuccessful, individual sub-band fits were made for each  $K'$  value to obtain sublevel parameters for each  $K$  sublevel of the anti-symmetric amino-wagging state.

In the far-IR spectrum of hydrazine vapor, torsional vibration bands with centers at 376.7, 665.9, and 289.5  $\text{cm}^{-1}$  correspond to transitions  $0 \rightarrow 1$ ,  $0 \rightarrow 2$ , and  $1 \rightarrow 2$ , respec-

Compiled from multiple sources, including [313, 444–450].

tively [339, 456]. The fine structure of rotational-vibrational bands is divided into two series, one with  $\Delta J = 0$ ,  $\Delta K = \pm 1$ , the other with  $\Delta J = \pm 1$ ,  $\Delta K = \pm 1$ . The Q branch is irregularly spaced near the center of the band, indicating that the symmetry factor is very small. The characteristic deformation vibrations of a pyramidal NH<sub>2</sub> consist of bending, twisting, and wagging modes. The bending and twisting modes correspond to the degenerate deformations of ammonia [457]. Hydrazine has three large-amplitude motions, two NH<sub>2</sub> wagging vibrations, and a torsional vibration. The torsional band in a range of 200 to 450 cm<sup>-1</sup> is ideal for testing theoretical models since it is the lowest vibration in the hydrazine molecule and is far from the higher-frequency vibrations, which might interfere. The torsional band of hydrazine is a b-type band, having the rotational selection rules  $\Delta K_a = \pm 1$ ,  $\Delta J = 0, \pm 1$ . The most distinctive feature of this band is a series of nearly equidistant Q-branch heads that degrade slightly toward the red. Under high resolution, one can resolve many regular series of R-branch lines [453]. However, P-branch lines could not yet be assigned. The barrier height for internal rotation was estimated to be approximately  $2100 \pm 50$  cm<sup>-1</sup>. Because tunneling splitting complicates the spectrum badly, it is difficult to give a more accurate estimate based on IR spectra alone. Some of the tunneling parameters in the torsionally excited state

were determined precisely. The torsional splitting in the torsionally excited state is 1824 MHz, compared to 5.8 MHz in the ground state. The inversion splitting found in the torsionally excited state is 7976 MHz. It is surprisingly smaller than the inversion splitting of the ground state, which is 16040 MHz.

Far-IR absorption lines of hydrazine can be assigned by a laser technique. Far-IR laser transitions for hydrazine can be generated by optical pumping with known laser lines [458]. For  $\text{N}_2\text{H}_4$ , assignments have been found for 14 new transition systems and verified for 5 others.

With 228 known far-IR (FIR) laser emissions, hydrazine is one of the most prolific laser active molecules after methanol. But due to the complexity of its rovibrational spectrum, only a few assignments of hydrazine FIR laser transitions are found in the literature [459, 460].

Rotational barriers are evident from two-dimensional inversion on the potential function for hydrazine determined from rotation-vibration spectra. The two-dimensional potential function for the inversion of the amino groups in hydrazine was obtained from a fit to the available IR and microwave data [403]. The barriers of 3408 and 2016  $\text{cm}^{-1}$  were calculated for the symmetric and anti-symmetric inversions of both amino groups, respectively. Contrary to earlier assumptions, a large potential coupling between the inversions of the amino groups was found [404]. The strong bands at 780 and 937  $\text{cm}^{-1}$  were assigned to the symmetric and anti-symmetric amino-wagging vibrations, respectively. When examining the 937  $\text{cm}^{-1}$  band of hydrazine vapor with a resolving power of 0.3  $\text{cm}^{-1}$ , it was found that every vibration-rotation band split into four components and that the amount of splitting depended only slightly upon the rotational quantum number [450]. At such a high resolution, described in IR spectroscopy lingo, the IR spectrum of hydrazine looks like the proverbial “picket fence.” This fine structure was explained by a vibration in which the wagging motions of the two amino groups take place anti-symmetrically with respect to the  $C_2$  axis, that along this axis an appreciable inversion takes place, and that such an inversion results in four equivalent equilibrium conformations. The barrier height between every two adjacent equilibrium conformations was 2620  $\text{cm}^{-1}$ .

A convenient source of IR for various analytical applications is the diode laser. Absorption measurements of pure hydrazine and MMH were recorded in an optical absorption cell (3 passes, 50 cm/pass) at low pressure (0–35 mm Hg) using a tunable external-cavity diode laser (ECDL), operating in a range of 6350 to 6650  $\text{cm}^{-1}$  (1.49 to 1.58  $\mu\text{m}$ ) [461, 462]. Peak absorption cross-sectional measurements of hydrazine and MMH, as determined from fixed-wavelength absorption measurements recorded at various pressures, were found to be  $\alpha_e/\nu = 0.163 \pm 0.003 \text{ cm}^{-1} \text{ atm}^{-1}$  at 6495  $\text{cm}^{-1}$  ( $\lambda = 1539.6 \text{ nm}$ ) and  $\alpha_e/\nu = 0.152 \pm 0.003 \text{ cm}^{-1} \text{ atm}^{-1}$  at 6560  $\text{cm}^{-1}$  ( $\lambda = 1524.4 \text{ nm}$ ), respectively. The measurements represent the first high-resolution survey spectra of these hydrazines in the near IR. These measurements will form the basis for the design of a diode-laser-based leak detection system for the Space Shuttle launch pad.

IR line positions, line strengths, and pressure-broadening coefficients are required to determine absolute trace gas concentrations from high-resolution absorption spectra. These values were measured for the IR absorption lines in the  $\nu_{12}$  band (anti-symmetric wag) of hydrazine between 965.4 and 965.7  $\text{cm}^{-1}$  using a high-resolution tunable diode laser system with 0.0006  $\text{cm}^{-1}$  spectral resolution and an 18-m pathlength multiple-pass absorption cell [463]. A continuous flow of hydrazine diluted to 100–500 ppm in nitrogen at pressures between 0.013 and 6.7 kPa (0.1 and 50 mm Hg) was used to prevent decomposition in the sampling cell. These results were used to construct a HITRAN-format line list that can be used both to spectroscopically distinguish hydrazine from other components and to determine its concentration in complex gas mixtures. See also [464].

The amino-wagging tunneling process in hydrazine was treated using the generalized internal-axis-method-like method developed by Hougen and Coudert, and Hamiltonian matrix elements were derived for each symmetry species in the combined group-theoretical and IAM-like treatment [465]. Ground-state microwave absorption transition data of hydrazine were analyzed again in this treatment to determine axis-switching angles for the amino-wagging tunneling process.

A high-resolution IR spectrum of hydrazine has been recorded in the 729–1198  $\text{cm}^{-1}$  region (the  $\nu_{12}$  anti-symmetric wagging band) with a resolution of 0.002  $\text{cm}^{-1}$  [466]. About 1350 transitions with  $K'$  from 7 to 13 have been assigned, and about 2350 transitions with lower values of  $K'$  were reanalyzed with the improved precision. The effective parameters were calculated separately for each value of  $K'$  using the Hougen-Ohashi Hamiltonian for hydrazine. The extended assignment completed the analysis of the  $\nu_{12}$  band of hydrazine.

In addition, 472 new rotational transitions in the vibrational ground state of hydrazine have been measured in the submillimeter range from 345 to 410 GHz [467]. Most recorded lines form eight  $K = 2 \leftarrow 1Q$  branches with  $J \leq 30$ , each branch being split due to internal rotation in hydrazine. New rotational transitions together with 443 that were previously known have been fitted to an effective group-theoretical Hamiltonian originally developed by Hougen 1981. For all 915 rotational transitions an overall standard deviation of the fit of 0.59 MHz was obtained using 32 parameters. These were 14 asymmetric rotor constants, 16  $\text{NH}_2$  inversion parameters, and 2 internal rotation parameters.

A very weak N–N stretching band ( $\nu_5$ ) in the IR spectrum of hydrazine was unambiguously assigned [468]. Almost 1500 transitions with a resolution of 0.002  $\text{cm}^{-1}$  for  $K'$  from 0 to 6 and for all symmetry species have been analyzed. The band center was determined at 1077  $\text{cm}^{-1}$ , much higher than previously expected.

A weak fundamental symmetric amino-wagging band,  $\nu_6$ , was assigned in the high-resolution FTIR spectrum of hydrazine [469]. An analysis of the Fermi-type resonance between the  $\nu_6$  and the third excited torsional state,  $3\nu_7$ , was performed, and a global fitting was carried out taking into account 3392 lines of the  $\nu_6$  band (for  $K'$  from

0 to 10 and for all symmetry species) and 428 lines of the  $3\nu_7$  band (for  $K'$  from 3 to 9 and only for the symmetry species in resonance). For all 3820 rovibrational transitions an overall standard deviation of the fit of  $0.019\text{ cm}^{-1}$  was obtained. The band centers of the symmetric wagging state and the third torsional were determined at  $795.137$  and  $860.138\text{ cm}^{-1}$ , respectively. IR and Raman spectra allow the distinction between singly and doubly protonated hydrazinium ions [470].

#### 2.4.2.1 IR Spectra of Solid Hydrazine, Adsorbed Hydrazine, and Matrix-Isolated Solid Hydrazine

Thin films of hydrazine or MMH or their decomposition products that may condense on cryocooled germanium optical windows of sensors on satellites in outer space might block IR transmittance. Therefore, IR absorption spectra of thin films of frozen  $\text{N}_2\text{H}_4$  or MMH on cold germanium windows were measured and interpreted by Fourier transform analysis [471, 472]. The substrate holders were cooled to 80 K (liquid nitrogen) or 20 K (cold helium gas) [473]. A dual-angle laser interference technique was used to determine the thickness and the refractive index of the thin hydrazine films. In addition, a quartz crystal microbalance was used to weigh the amount and give the average loading density. Plume contamination by unreacted propellants or combustion products is a concern for many satellite and space probe missions using hydrazine propellants.

The lack of some IR absorption bands reported by other investigators for crystalline  $\text{N}_2\text{H}_4$  suggested that the thin films deposited at very low pressures ( $10^{-7}\text{ mm Hg}$ ) were actually supercooled liquids and not truly crystalline hydrazine. The same has been observed in hydrazine droplets formed by flash evaporating liquid hydrazine into a vacuum and forming an aerosol [36]. The sudden cooling did not allow crystals to order themselves and the droplets consisted of mixtures of disordered and crystalline phases. A disordered phase was observed at initial cell temperatures of 230 to 180 K, and a transition to a crystalline phase occurred around 175 to 180 K. The gas (and particles suspended in it) was approximately 10 K warmer than the vacuum cell. At lower temperatures the IR bands at  $3000$  to  $3400\text{ cm}^{-1}$  became progressively sharper, indicating that the regularity in the crystals improved as the temperature was lowered to 110 K. At the lowest temperature, the two peaks split into doublets. Some self-annealing (due to the heat of condensation released at the moment of phase change) occurred before the particles had a chance to impinge on the wall of the chamber or bump into another particle with a different temperature. Such studies were initially started to study hydrazine clouds in planets with ammonia atmospheres but may also find application in detecting rocket propellant leaking from satellites in space or looking at the cloud generated when hitting a wayward satellite with an antiballistic missile.

#### 2.4.3 Raman Fluorescence Spectra of Hydrazine

Raman spectra are mostly of scientific interest and are not used for actual practical analytical methods like IR spectroscopy. Raman spectra, in combination with IR spectra, are useful in identifying fundamental vibrations in hydrazine molecules.

### 2.4.3.1 Raman Spectra of Liquid Hydrazine

Two sets of five sharp lines were observed in liquid hydrazine excited with the 404.7 or 435.9 nm lines of mercury [429, 439]. Two lines were at shifts of 90 and 112  $\text{cm}^{-1}$ , and three lines were at shifts of 3212, 3289, and 3339  $\text{cm}^{-1}$ . The latter three agreed very well with the triplet observed in liquid ammonia and have been assigned to N—H vibrations. The first two were unique to hydrazine. The weak line at 900  $\text{cm}^{-1}$  could have been caused by residual water in the sample. Raman and IR spectra were obtained on samples of  $\text{N}_2\text{H}_4$  and  $\text{N}_2\text{D}_4$  of identical purity and are shown in Table 36 for comparison [474].

**Table 36:** Raman and IR spectra of liquid  $\text{N}_2\text{H}_4$  and  $\text{N}_2\text{D}_4$ .

| $\text{N}_2\text{H}_4$        |                        |                               |                        | $\text{N}_2\text{D}_4$        |           |                               |           |

<sup>a</sup> Intensity on a scale from 0 to 10 (estimated)

<sup>b</sup> Intensity on a scale from very weak to very strong (estimated)

Data source: [474]

The 435.8-nm line of mercury was used for excitation and the spectra were recorded on photographic plates and with an electric photometer. The agreement between the two sets of data for the two isotopomers was quite good. See also [475, 476].

Raman displacements, relative intensities, and depolarization factors for liquid hydrazine were measured at room temperature [313]. All available literature data con-

cerning the structure, Raman and IR spectra, frequency assignments, and dipole moment measurements were collected and examined in a search for the most reliable values. The results of normal coordinate treatment based on the  $C_2$  model were reported, and frequency assignments were reviewed. Also, calculated thermodynamic properties for 273.16 to 1000 K based on the rigid rotator harmonic oscillator approximation were provided.

#### 2.4.3.2 Raman Spectra of Solid Hydrazine

Since earlier Raman spectra of crystalline  $N_2H_4$  and  $N_2D_4$  had been obtained only with mercury line excitation [366], the spectra of both compounds were reinvestigated using the 514.5-nm line of an argon ion laser, resulting in good agreement between the two sets of data (Table 37) [445]. New, weak, previously not observed lines were reported at 818, 994, and  $1028\text{ cm}^{-1}$  for  $N_2H_4$  and at 333, 778, and  $852\text{ cm}^{-1}$  for  $N_2D_4$ .

Raman spectra provide information on the crystal structure of solid hydrazine. If solid hydrazine crystallized in the  $C_{2h}^2$  space group (see space group assignments based on X-ray and NMR data, Section 2.3.4), one should expect only six Raman-active lattice modes. An inspection of the Raman spectrum in the lattice region shows five strong, sharp lines and three weak, sharp lines for  $N_2H_4$  and six strong, sharp lines with an additional four weaker ones for  $N_2D_4$ . There does not appear to be any way in which these lines can be assigned as three libration and three translations, even if one considers phonon bands. Therefore, the  $C_{2h}^2$  space-group symmetry with two molecules per unit cell must be ruled out. It is possible to reconcile the Raman spectra with a  $C_{2h}$  space group with  $Z = 4$ . Phase transitions in solid hydrazine/water mixtures result in changes of the Raman spectra of the solid samples [123].

#### 2.4.3.3 Raman Spectra of Hydrazine Vapor

Based on measurements obtained using the 514.5-nm line of an argon ion laser [445], the Raman spectra of hydrazine  $N_2H_4$  vapor has five pronounced, polarized lines at 3398, 3329, 3302, 3266, and  $1076\text{ cm}^{-1}$ . For a molecule with  $C_2$  symmetry one expects two N—H stretching vibrations, resulting in polarized Raman bands.

Unlike in earlier studies, the Raman line at  $3398\text{ cm}^{-1}$  (a normal mode) is assigned to the  $NH_2$  anti-symmetric stretch of symmetry " $a$ " and the line at  $3329\text{ cm}^{-1}$ , the strongest line in the Raman spectrum, is assigned to an  $NH_2$  symmetric stretch of the corresponding symmetry. The band at  $1076\text{ cm}^{-1}$  is the N—N stretch. Two lines at 3302 and  $3266\text{ cm}^{-1}$  are overtones of two  $NH_2$  deformations. The strongest Raman line was reported at  $1564\text{ cm}^{-1}$  in [477], but Durig et al. did not observe any Raman scattering in this region. The two weaker lines at 1076 and  $3332\text{ cm}^{-1}$  agreed well among the two groups of authors. In the Raman spectrum of  $N_2D_4$  vapor, the lines at 2442, 2422, and  $2358\text{ cm}^{-1}$  were assigned to  $\nu_1$ ,  $\nu_2$ , and  $2\nu_3$ , respectively. The line at  $1031\text{ cm}^{-1}$  is the N—N stretch. The line at  $930\text{ cm}^{-1}$  is an  $ND_2$  wagging vibration. Isotope substitution has again proven to be a valuable tool in achieving assignments of frequencies to molecular vibrations. The various lines for both  $N_2H_4$  and  $N_2D_4$  are summarized in Table 38.

**Table 37:** Observed Raman spectra of crystalline  $\text{N}_2\text{H}_4$  and  $\text{N}_2\text{D}_4$ .

| Frequency, $\text{cm}^{-1}$ |    | Assignment and description |    |                                                            |

#### 2.4.4 Refractive Index of Hydrazine

The measurement of the index of refraction is a quickly performed test for purity of liquid compounds or for the quantitative analysis of binary mixtures. The results are summarized in Table 39.

Additional index of refraction data for alkyhydrazines are in the chapters on dimethylhydrazines and methylhydrazine. The index of refraction of hydrazine has been determined for hydrazine at various temperatures using several different wavelengths. The results are summarized in Table 40. The refractive index of hydrazine can be plotted as a function of temperature, and a linear relationship is obtained (Figure 35).

**Table 38:** Raman spectra of hydrazine and tetradeuterohydrazine vapor.

Figure 35: Refractive index of anhydrous hydrazine at sodium D line (5893 Å). (Reproduced and modified from [171].)

The molecular refraction of hydrazine at the D-line wavelength is 8.892 [167]. Very few good summaries of the refractive index and molecular refraction data of hydrazine derivatives exist [483].

The index of refraction of binary hydrazine mixtures can be used as a method of quick quantitative analysis. A calibration curve must be prepared first. A refractometric method of analysis of binary hydrazine-water or hydrazine/UDMH mixtures has been described [480]. The index of refraction data was measured at two temperatures, 293 and 298 K, over the entire range of compositions. Only the 298 K data are illustrated here (Figure 36).

**Figure 36:** Refractive index of hydrazine mixtures at 298 K. (Reprinted and modified from [480].)

The refractive index of  $N_2H_4$ /UDMH mixtures will be described further in the chapter on dimethylhydrazines. As can be seen in the preceding graph, comparison of the slopes of the two curves revealed that the  $N_2H_4$ / $H_2O$  system showed a more pro-

nounced variation of the refractive index as a function of composition than did the  $\text{N}_2\text{H}_4/\text{UDMH}$  system. The refractive index has been considered as an analysis method for hydrazine/water mixtures [484]. The advantage of the method is that it can be performed by untrained personnel. The disadvantage is that it is not specific to water or hydrazine in the presence of other contaminants. Also, it takes a relatively long time for the instrument and sample to attain constant temperature. The refractive index has been proposed as a field analysis method for a hydrazine propellant blend nominally containing 30% water [485]. A graph for the refractive index of aqueous HN solutions at 298 K was already shown in *Encyclopedia of Oxidizers*, in the chapter “Hydrazinium Salt Oxidizers.”

## 2.5 Microwave Spectra of Hydrazine

Microwave spectra extend the IR toward very long wavelengths on the order of millimeters instead of micrometers. Because of the lesser quantum energy, microwave spectra reveal details of low-energy molecular transitions, such as individual rotation energy states and their thawing temperatures. Microwave absorption of hydrazine would have to be known for the design of microwave-powered initiation of hydrazine decomposition in monopropellant thrusters.

Because ammonia and amino radicals have already been detected in interstellar gas, it should come as no surprise if one of these days hydrazine is also identified in interstellar gas by its microwave absorption.

Molecules with large-amplitude vibrational motions such as inversion or internal rotation show very complicated IR and microwave spectra. In hydrazine, three large-amplitude motions are possible, two inversions and an internal rotation of the two amino groups. Based on repeated microwave measurements, a revised theory of the rotational energies in the ground vibrational state was developed. The eight series of the Q-branch transition  $\Delta J = 0, K = 1 \leftarrow 0$  of hydrazine vapor were observed at frequencies up to 130 GHz [486, 487]. The inversion splitting for the  $J_K$  level may be expressed by

$$\nu = 16040.2 - 1.53J(J+1) - 25.9K^2, \quad \nu \text{ in MHz}$$

The rotational constants are

$$A = 143467.6 \text{ MHz}$$

$$B = 24083.0 \text{ MHz}$$

$$C = 24070.1 \text{ MHz}$$

The height of the internal barrier of rotation was found to be equivalent to  $1240 \pm 50 \text{ cm}^{-1}$ , assuming a twofold potential barrier. Other authors found the rotational barrier to be approximately 13.14 kJ/mol (3.14 kcal/mol) [378]. In a range of 4.7 to 30 GHz,

about 200 lines were found, and all exhibited quadratic Stark effects [488]. The spectrum is complicated by the internal rotation of one amino group with respect to the other and by the inversion of each amino group like motions in ammonia or methylamine [378]. For some lines the hyperfine structures due to the nuclear quadrupole coupling of two nitrogen nuclei with the overall and internal rotation of the molecule could be observed. It is possible to excite selective vibrations with IR radiation and then conduct double-resonance spectroscopy of selected molecule segments, e.g., the anti-symmetric amino group wagging with microwaves [489]. The anti-symmetric amino-wagging band lies in the 10- $\mu\text{m}$  region. Nearly 200 microwave transitions were measured in a frequency range of 6–60 GHz using  $\text{N}_2\text{O}$  and isotopic  $\text{CO}_2$  masers as the radiation source. Among the microwave transitions, 27 were assigned as those of the ground vibrational state and 9 as those of the vibrationally excited state. About 20 IR absorption lines were assigned based on the double resonance measurements. The excited-state rotational constants, the internal rotation splittings, the inversion splittings, and even Coriolis splittings were determined accurately.

Hydrazine can serve as a lasing medium. In addition to microwave absorption, microwave emission in the submillimeter range has also been observed with hydrazine molecules excited by radiation from a carbon dioxide laser [490, 491].

Water, hydrazine, and hydrogen peroxide all have a tendency to supercool. Dielectric relaxation studies of aqueous solutions of hydrazine and hydrogen peroxide in the neighborhood of their glass transition temperatures,  $T_g$ , showed that these solutions behave in a rather simple manner [492]. Their relaxations near  $T_g$  were more nearly exponential than in most other cases, and they showed essentially no secondary relaxations. Supercooled hydrazine solutions were the more stable solutions of the three.

Microwave spectra of deuterium-substituted hydrazine  $\text{N}_2\text{D}_4$  or HDNNDH helped in the assignment of vibrational bands [493]. When measuring the microwave spectrum of  $\text{N}_2\text{D}_4$  in a range of 8 to 100 GHz, an inversion splitting was observed at 443 MHz (compared to 7974 MHz for  $\text{N}_2\text{H}_4$ ) [494]. The rotational constants for  $\text{N}_2\text{D}_4$  were

$$A = 74724.3 \text{ MHz}$$

$$B = 18501.9 \text{ MHz}$$

$$C = 18437.5 \text{ MHz}$$

The barrier height to inversion was  $2120 \text{ cm}^{-1}$ .

## 2.6 Photoelectron (ESCA, XPS) Spectra of Hydrazine

ESCA (or XPS) is a spectroscopic method that can be applied to vapors and solid surfaces. Depending on the objective of the analysis and the range of atomic weights to be scanned, resonance lines of noble gases in vacuum UV or monochromatic X-

rays (magnesium or aluminum) are used to excite photoelectrons that are then passed through a monochromator, and their energy and intensity are measured. In solid materials, only a very thin surface layer is analyzed, usually only 5 nm deep. For gaseous samples, less energetic photons (vacuum UV as opposed to X-rays) are used to excite electron spectra. Hydrazine XPS spectra have been measured with the 30.4-nm He(II) resonance line [495, 496], 58.4-nm He(I) line [497], or magnesium  $K_{\alpha}$  lines [498, 499]. The high-resolution photoelectron spectrum of hydrazine vapor shows two pairs of overlapping bands. The experimental vertical ionization energies are 9.91, 10.64, 15.61, and 16.66 eV. The splitting of the two bands indicates the energy variation of electrons coming from two different rotational structures of hydrazine. The letters represent the originating orbitals [ $n(\text{N})$ ,  $\sigma(\text{N}-\text{N})$ ,  $\pi(\text{NH}_2)$ ] assigned to the respective electrons in the photoelectron spectrum.

Photoelectron spectroscopy has developed into a very useful tool for conformational analysis, and ESCA-XPS spectra permit quantitative determination of the interaction of molecular orbitals by measuring the ionization energies of various molecular valence orbitals with high precision. Different conformations are characterized by different energy states and usually show up as separate or split peaks in the ESCA spectrum. A splitting of 38.59 kJ/mol (0.4 eV) in the nitrogen nonbonding orbitals of hydrazine was derived from the initially obtained low-resolution spectra [500]. More sensitive instrumentation has allowed refinement of these data to 70.04 kJ/mol (0.73 eV) [496]. The measured energy was assigned to specific orbital interactions, and splitting of the peaks was derived by CNDO/2 and MINDO/2 calculations using a “sum rule” [497]. The sum rule states that the sum of experimental ionization energies may be reproduced by the sum of localized-orbital ionization energies. For a dihedral angle of  $95^\circ$ , the CNDO/2 method is more accurate than the MINDO/2 method.

## 2.7 Neutron and Electron Diffraction Spectra

In addition to XRD, neutron and electron diffraction spectra have been used to investigate the structure of hydrazine and its compounds. Electron diffraction studies of hydrazine vapor showed no evidence of dimerization [501]. The N—N bond distance was  $(1.47 \pm 0.02) \times 10^{-10}$  m, the N—H bond distance was  $(1.04 \pm 0.06) \times 10^{-10}$  m, and the N—N—H bond angle was  $108 \pm 8^\circ$ . See also [388].

## 2.8 Electrical Properties of Hydrazine

### 2.8.1 Electrical Conductivity of Hydrazine

Hydrazine is an electrolyte, and any dissolved salt will greatly increase its electrical conductivity. Often trace amounts of contaminants, such as water or carbon dioxide,

will increase its conductivity. The small conductivity in ultrapure hydrazine may be due to autodissociation. Like water or ammonia, hydrazine undergoes molecular autoionization to form its acid and base conjugates:

### 2.8.2 Dielectric Constant of Hydrazine

The dielectric constant (abbreviation DC, symbol  $\epsilon$ ) of hydrazine has been determined to be between 58.5 and 51.7 between 273 and 298 K [502, 503]. The data, also compiled in Table 41, can be represented by the following equations:

$$\epsilon = 58.5 - 0.3253t + 2.8 \times 10^{-3}t^2 - 2.67 \times 10^{-5}t^3$$

where  $\epsilon$  is the dielectric constant (dimensionless) and  $t$  is the temperature in  $^{\circ}\text{C}$ , or

$$\epsilon = 266.82 - 1.2153T + 11.6565 \times 10^{-3}T^2$$

where  $\epsilon$  is the dielectric constant (dimensionless) and  $T$  is the temperature in kelvin.

**Table 41:** Dielectric constants of hydrazines.

| Compound                        | Temperature, K | Dielectric constant | References      |
|---------------------------------|----------------|---------------------|-----------------|

The DC of hydrazine is quite high, 51.7 at 298 K, compared to 15 for ammonia or 81 for water. Electrolytes dissolved in hydrazine will thus become ionized almost as easily as in water. As a result, the electrical conductivity of hydrazine changes drastically as soon as minor impurities, such as carbazic acid formed from carbon dioxide in the air, become dissolved in it.

## 2.9 Nuclear Magnetic Resonance Spectra of Hydrazine

NMR spectra of hydrazine, either from the nitrogen nuclei or the hydrogen nuclei (protons), are useful for determining the structure of hydrazine molecules and the amount of proton exchange and hydrogen bonding among them. The machines used to perform this type of analysis and their magnets are usually very heavy, so this is not an analytical method suitable for portable toxic vapor analyzers.

The measurements of  $^{14}\text{N}$  nuclear quadrupole resonance cross relaxation in hydrazine [362, 389] and hydrazine hydrate [369, 505] have helped to elucidate the internal structure of these molecules. By varying the temperature of a solid hydrazine sample from 274 down to 77 K, four resonance lines were observed with almost equal intensity. At 77 K, the resonance frequencies were 1.8910, 1.9950, 2.6470, and 2.6717 MHz, respectively. When the sample was allowed to thaw, they faded out at 300 K.

On further study using a saturation recovery method, six resonance lines due to two nonequivalent positions for each  $^{14}\text{N}$  nucleus in addition to the nonaxial symmetry were observed [361, 506]. The observed frequencies were 4.611, 2.617, and 1.994 MHz for system II at 77 K. The spin-lattice relaxation of the nuclear spin is caused by the thermal transitions between the energy levels of  $\Delta m = \pm 1$  and  $\pm 2$ . It has been proposed that the crystal force field around the  $^{14}\text{N}$  nuclei deviates strongly from the axial symmetry. Together with data derived from X-ray analysis, this suggested that the crystal is a monoclinic (space group  $C2_2$ ) having two molecules in a unit cell.

With improved resolution, the fine structure of NQR lines of  $^{14}\text{N}$  in a solid hydrazine single crystal could also be observed [507]. The fine structure was found in all six lines. The line splitting in the two lines with the highest frequency was especially clear and well resolved. The fine structures consisted of at least four lines spreading over a bandwidth of 420 to 680 Hz. This fine-splitting was attributed to interaction with neighboring hydrogen atoms. It was too great to be interpreted by the direct nuclear magnetic dipole-dipole interaction between nitrogen and surrounding nuclei. Electron-coupled nuclear spin interaction was successfully applied to explain the fine-line structure of other molecules. The temperature dependence of spin-lattice relaxation correlates with the temperature dependence of fluid viscosity [508]. The quadrupole hyperfine structure in hydrazine, a molecule that exhibits significant tunneling splittings as a result of large-amplitude inversion and internal rotation motion, may be caused by tunneling motions [509]. The following quadrupole coupling constants were derived from  $^{14}\text{N}$  line widths:  $\Delta H_{\text{ms}} = 0.41 \pm 0.01 \text{ G}$ ,  $T_2 = 2.52 \times 10^{-3} \text{ s}$ ,  $(e^2qQ)/h = 4.8213 \text{ MHz}$ ,  $\eta = 0.8070$ ,  $\tau_q = 0.95 \times 10^{-12} \text{ s}$ ,  $\tau_c = 0.78 \times 10^{-11} \text{ s}$ ,  $\tau_c/\tau_q = 12.2$  [510].

The  $^{14}\text{N}$  NQR spectrum of hydrazine hydrate between 4.2 and 140 K consists of two high-frequency lines (4550 kHz at 4 K) and a low-frequency line (2560 kHz) [369, 511]. Both lines weaken and become extinct above 140 K. The activation energy of this molecular motion (most likely rotation or switching motion of a hydrogen bond),

which becomes active at about 120 K, is 31.4 kJ/mol (7.5 kcal/mol). One can also observe an echo envelope modulation due to intramolecular dipolar coupling. This molecular motion is different from that of anhydrous hydrazine, whose activation energy is 59.8 kJ/mol (14.3 kcal/mol), where a hydrazine molecule begins a type of turnover motion about an axis perpendicular to the N—N bond at temperatures above 245 K (Zussman and Alexander 1968). See also [512, 513].

Nuclear quadrupole magnetic resonance measurements can supply important information on internal motion in solids. Line width and spin relaxation time measurements of nuclei are especially helpful. Measurements of the  $^{14}\text{N}$  atom in frozen hydrazine between 200 and 260 K have shown that molecules remain sufficiently mobile to interchange  $^{14}\text{N}$  nuclei between two crystallographically nonequivalent sites. The molecular motion had an activation energy of  $59.8 \pm 1.7$  kJ/mol ( $14.3 \pm 0.4$  kcal/mol) and proceeded at a rate of  $\sim 2500\text{ s}^{-1}$  at 250 K [368]. A continuation of this study provided relative orientations of the electric field gradient (EFG) tensors [514]. The two nonequivalent nitrogen atoms in hydrazine interchange sites. Spin-lattice relaxation measurements on all six  $^{14}\text{N}$  NQR lines were done at 228 K. According to these measurements, there are two molecules in a unit cell related to each other by inversion. The two nitrogen atoms in the molecule are nonequivalent and have slightly different quadrupole parameters. At 228 K these are  $e^2q^I Q = 4.745$  MHz,  $\nu^I = 0.820$ ,  $e^2q^{II} Q = 4.738$  MHz, and  $\nu^{II} = 0.785$ . The angles between the tensor directions are  $\Phi_{XX} = 93.7^\circ$ ,  $\Phi_{YY} = 16.7^\circ$ , and  $\Phi_{ZZ} = 91.0^\circ$ .

## 2.10 Redox Potential of Hydrazine in Solution

The use of dilute hydrazine hydrate solutions in fuel cells opens new applications for hydrazine as an energy carrier. Electrochemical methods for the analysis and detection of hydrazine will be discussed in Section 3.6.10.

Based on experimental evidence obtained during the oxidation of hydrazine in acid and alkaline media it was concluded that the oxidation of hydrazine occurs not primarily via a hydrogen oxidation mechanism, as previously suggested, but via a sequential oxidation of radicals (intermediates) derivable from hydrazine [515]. It was furthermore concluded that the electrode surface characteristics affect the potential of oxidation, while the rest potential is controlled by the subsequent formation of radicals.

## 3 Chemical Properties of Hydrazine

### 3.1 Reactions of Hydrazine

#### 3.1.1 Reactions of Hydrazine with Inorganic Compounds

Hydrazine is very reactive and reacts with a multitude of inorganic compounds. Hydrazine as a base forms a wide range of hydrazinium salts, several of which are discussed in *Encyclopedia of Oxidizers*, in the chapter “Hydrazinium Salt Oxidizers.” Hydrazine and hydrazine derivatives as ligands in metal complexes open up an entire new chapter of hydrazine compounds, best summarized in a book by Patil and Ratan [516].

##### 3.1.1.1 Oxidation of Hydrazine (Hydrate) in Solution

Although the two adjacent nitrogen atoms in hydrazine should favor the formation of nitrogen when the hydrogen is abstracted by oxidation, this seemingly simplest path of reaction is hardly ever followed during oxidation reactions. The oxidation of hydrazine in aqueous solutions can happen in many ways, depending on the pH and the presence or absence of trace amounts of transition metals, which act as catalysts. A summary contains sections on thermochemical properties of hydrazine, reaction stoichiometry and kinetics studies, and studies of reaction intermediates [517]. Depending on the type of oxidant used, molecular nitrogen was found only in a few cases to be the sole oxidation product [518]. The multiplicity of oxidation products also made it very difficult to find an oxidizing agent that would react in stoichiometric ratios with hydrazine and could be used for quantitative oxidimetric volumetric analysis. In addition to molecular nitrogen, the compounds ammonia, hydrazoic acid, and diazene have been observed as oxidation products of hydrazine, depending on the type of oxidizer used.

##### 3.1.1.2 Kinetics of Hydrazine Reactions with Oxygen and Ozone

The kinetics of the reaction of hydrazine vapor with oxygen or ozone are of interest when one must predict the environmental fate of hydrazine released into the atmosphere. Because hydrazine is a strong reducing agent and hydrazine vapor will autoignite with oxygen (at higher than atmospheric pressure) and ozone (over a wide pressure range down to very low pressures), kinetic studies must be done outside the range of autoignition. This can be achieved either by working at very low pressures or by dilution with an inert gas.

Hydrazine-oxygen and hydrazine-ozone reactions in aqueous solutions are of interest for the design of wastewater treatment plants. Sometimes oxygen or ozone wastewater treatment is combined with other agents (UV, ultrasound, microwaves, catalysts) to speed up the reaction. This application will be discussed in Section 7.12.1.3.

The main industrial application of hydrazine hydrate is for boiler feedwater de-oxygenation in steam power plants. This reaction is done mostly with the addition of water-soluble catalysts and is outside the scope of this book on rocket propellants.

Oxygen-hydrazine reactions can lead to spontaneous ignition and have been the cause of a few accidents. Under elevated pressure, dioxygen is a very active oxidant for hydrazine. The flammable range and autoignition temperatures of hydrazine in air and hydrazine in oxygen will be covered in Section 8.1. Flame speeds of hydrazine flames are described in Section 4.14.1. The current section deals only with academic treatises on hydrazine oxidation kinetics, experiments conducted at low pressures or in high dilution, and computational models for such reactions.

### 3.1.1.3 Vapor-Phase Autoxidation Reactions

Early studies of the reaction of hydrazine vapor with oxygen led to the conclusion that oxidation proceeds by a series of successive radical mechanisms and does not seem to involve either long or branching chains [519]. But the reaction slowed down by the increase of glass surface : volume ratios and/or the addition of ethylene as a radical scavenger. The reaction was studied at 373–433 K and up to 1.32 kPa (10 mm Hg) pressure. These results were confirmed in a later study [520]. The thermal gas-phase reaction showed none of the chain reaction characteristics found with hydrocarbon oxidation. It was found to be predominantly a bimolecular surface reaction with an activation energy of 26.9 kJ/mol (6.430 kcal/mol) (below 373 K). The rate increased linearly with the oxygen concentration. Nitrogen or water-vapor addition had no effect on the kinetic rates.

The explosive oxidation of hydrazine (and ammonia) was studied by flash photolysis and kinetic spectroscopy [521]. The main reaction, which resulted in nitrogen as the end product, was suggested to proceed as a series of progressive dehydrogenation steps without fission of the N–N bond:

The hypothesis of nitrosamine formation in the oxidation of hydrazine was adopted by later investigators. Nitrosamine could be detected in the reaction of atomic oxygen and amino radicals. Another intermediate that has been so far neglected in the study of hydrazine flames but that was shown to occur in other flames and was blamed for high  $\text{NO}_x$  formation is the NNH fragment [522]. It is likely to be an intermediate in  $\text{NO}_x$  formation in hydrazine flames.

Measurements of hydrazine decay in air were done in Pyrex glass vessels, but the data were not yet fitted to a kinetic model [523]. A few years later, other investigators fitted the University of Leeds data to a kinetic model and found good agreement between measurements and predictions of the surface catalysis model [524].

Because of the strong nitrogen dilution, the oxidation of hydrazine vapor with oxygen in an adiabatic flow reactor was not accompanied by a luminous flame, but this experimental arrangement allows a more in-depth study of the kinetics than an atmospheric pressure flame [525]. The reaction rate was found to be dependent on the first power of hydrazine concentration but independent of oxygen concentration. The data indicated that decomposition and oxidation occurred simultaneously and at the same rate. The oxidation reaction rate was between that of dry and “wet” hydrazine decomposition. The activation energy of  $156 \pm 10 \text{ J/mol}$  ( $37.2 \pm 2.4 \text{ kcal/mol}$ ) was very similar to that of hydrazine decomposition ( $151 \text{ kJ/mol} = 36.2 \text{ kcal/mol}$ ). The pre-exponential factor was  $10^{9.91 \pm 0.54}$ . The adiabatic reaction temperature in these tests was 950–1010 K, the initial hydrazine concentration was  $0.4\text{--}1.4 \times 10^{-7} \text{ mol/cm}^3$ , and the hydrazine : oxygen equivalence ratio was 0.2–0.5 (lean mixtures). A mechanism by way of fission of the N–N bond and chain propagation through  $\text{HNO}$ ,  $\text{N}_2\text{H}_3$ ,  $\text{H}_2\text{NNO}$ , and  $\cdot\text{OH}$  radicals was proposed, but very little proof was offered [525]. The addition of NO, usually an active radical scavenger, failed to bring about a distinct change of the reaction rate. Thus, amino and hydrazino radicals may not play the same role in hydrazine oxidation as in hydrazine decomposition, or the decomposition of  $\text{H}_2\text{NNO}$  may generate new radicals. The ignition and combustion of hydrazine in dioxygen was interpreted as a branched chain reaction with some indication of self-inhibition [526]. At higher pressures, the critical conditions of ignition were determined by a competition of chain branching and wall-catalyzed recombination reactions.

The environmental fate of hydrazine vapors in the atmosphere of Earth, which is an autoxidation reaction, has been studied in laboratory chambers under carefully controlled conditions (see Section 10 on Environmental Effects). It was difficult to obtain reproducible results due to interaction of hydrazine vapors with the chamber wall material, outward diffusion of hydrazine through the polymer foils used as chamber materials, and inward diffusion of oxygen from the laboratory air into the test chambers.

The adsorption and autoxidation of hydrazine vapor on polymeric and metallic surfaces was often ignored during the design and operation of laboratory test animal exposure chambers in hydrazine toxicity studies, resulting in overdosing the poor animals [527].

Peroxide radicals formed by reactions of atomic hydrogen (and possibly hydrazyl radicals) with dioxygen were trapped from a low-pressure  $\text{O}_2/\text{N}_2\text{H}_4$  flame onto a cold finger situated in the resonator cavity of an electron proton resonance (EPR) spectrometer [528]. The flame temperature was 860 K at 1.56 kPa. The free radical survival was

enhanced by coating the walls of the apparatus with boric acid. A graphite capillary was used to intercept and eliminate atomic hydrogen between the flame and the cold finger, thus assuring that the EPR signal of  $\text{HOO}^\bullet$  could be recorded without interference from  $\text{H}^\bullet$ .

Dioxygen activation reactions which propagate through a four center two electron (4c-2e) bound species were computed using static DFT and *ab initio* quantum-chemical techniques and showed an oxidation pathway for hydrazine and its methylated analogues with dioxygen which involved formation of this unconventional 4c-2e bonded species in route to the oxidation products [529].

It has been inferred from experimental data that hydrazine oxidation and decomposition reactions occur via a branched-chain and a nonbranched-chain mechanism, respectively. The chain nature of these processes helps explain the observed regularities under the critical autoignition conditions, including their “anomalous” character and the combustion-to-explosion transition [530].

The kinetics and mechanisms of atmospheric reactions of hydrazine vapor and molecular dioxygen on singlet and triplet potential energy surfaces have been investigated using *ab initio* and DFT methods [531]. The results showed that a direct hydrogen abstraction mechanism is the most important pathway of reaction. Three pre-reactive complexes on the singlet and triplet potential energy surfaces were formed between hydrazine and molecular dioxygen. Seven different products were suggested, all of which have sufficient thermodynamic stability. The production of  $\text{HN}=\text{NH} + \text{H}_2\text{O}_2$  and  $\text{H}_2\text{N}_2(\text{OH})_2$  were the main reaction channels from a thermodynamic viewpoint. From a kinetic point of view, an  $\text{H}_2\text{NN} + \text{H}_2\text{O}_2$  adduct (on singlet state) and  $2\text{N}_2\text{H}_3 + 2\text{HO}_2$  adducts (on singlet and triplet states) after passing one corresponding low-level transition state were the most favored pathways of reaction.

#### 3.1.1.4 Liquid-Phase Autoxidation Reactions in Aqueous Solution

Autoxidation of dissolved hydrazine in water by interaction with atmospheric oxygen would occur in holding ponds, where hydrazine-contaminated wastewater is held while it awaits permanent decontamination. Autoxidation of aqueous hydrazine solutions is accelerated by dissolved transition metal ions, which are typically present as natural contaminants in tap water and most surface waters [532–535].

It is surprising to learn that hydrogen peroxide, an oxidant, has been found among the reaction products of hydrazine (a reductant) with air [536]. The presence of  $\text{H}_2\text{O}_2$  was proved by reaction with titanil sulfate. The autoxidation reaction seemed to be heterogeneous (surface catalyzed). The rate of oxidation was at a maximum in 0.01–0.03 M NaOH and dropped again in stronger alkaline solutions.

Studies of the reaction between hydrazine and oxygen at 298 and 343 K (25 and 70 °C) in alkaline solutions have shown that the observed rate is due to catalysis by traces of impurities [537]. Copper(II) and manganese(II) were the most active catalysts, and, under certain conditions, the copper(II)-catalyzed reaction appeared to be homogeneous. Manganese(II) salts will catalyze autoxidation of hydrazine in water [538].

Free radicals have been observed in the metabolic oxidation of hydrazine in blood during the oxidative metabolism of hydrazine in rat liver microsomes [539]. This observation suggests the involvement of the cytochrome P-450 enzyme system in the formation of hydrazine radicals, which may be a precursor of diimide during microsomal oxidation of hydrazine.

Hundreds of catalysts have been patented for the use of hydrazine hydrate for the boiler feedwater deoxygenation in steam power plants. Some of these compounds may also be useful for the decontamination of hydrazine-polluted wastewaters by autooxidation in ponds at atmospheric pressure and ambient temperature.

If hydrazine is spilled into environmental waters, once the dissolved oxygen is depleted by the reacting hydrazine, the only means of continuing the reaction is by diffusion of atmospheric oxygen across the air-water interface [540]. Many publications did not consider the diffusional source of oxygen when predicting the rate of survival of hydrazine when spilled into surface waters.

Most of the studies cited in the preceding discussion were performed with very dilute hydrazine hydrate solutions. The following reference deals with much higher concentrations. When 100% hydrazine hydrate (64% hydrazine) was stored in contact with air in Pyrex glass containers at room temperature, the concentration decreased from 64 to 45% within 160 d [541]. The hydrazine concentration of a 10% NaOH solution in hydrazine hydrate decreased at approximately the same rate. See also [517, 518].

#### 3.1.1.5 Kinetics of Reactions with Atomic Oxygen

Numerous investigators have studied the reaction of atomic oxygen with hydrazine vapor. This reaction will occur if hydrazine is released into the upper atmosphere and stratosphere. This reaction is peculiar in that not only does it exhibit chemiluminescence, but mass spectrometric studies have also shown that oxygen preferentially abstracts two hydrogen atoms from opposite ends of a molecule with the resulting formation of diazene [349]. Some of these studies were conducted using oxygen atoms and, in separate tests, hydrogen atoms to initiate hydrazine decomposition and comparing the results and different modes of hydrogen abstraction from hydrazine. In the remaining pages of this chapter, mass spectrometric studies are discussed first, followed by emission spectroscopic studies. The chemiluminescence of the reaction of atomic oxygen with hydrazine vapor can be used for the detection and analysis of hydrazine.

The thermochemical and kinetics properties of hydrogen abstraction from the hydrazine molecule by atomic oxygen were computed using high-level *ab initio* methods [542]. The properties along the reaction path were obtained using a dual-level methodology to build the minimum energy path with the potential energy surface method and thermochemical properties results. The thermal rate constants were calculated in the framework of variational transition-state theory. Energy wells on both sides of the reaction (reactants and products) were found and considered in the chem-

ical kinetics calculations. Additionally, the product yields were investigated by means of a study of the triplet and singlet surfaces of the reaction

### 3.1.1.6 Mass Spectra of Reaction Products of Atomic Oxygen with Hydrazines

When studying the  $\text{O}^\bullet + \text{N}_2\text{H}_4$  reaction in crossed molecular beams, it was noted that the reaction

in which two hydrogens are removed, occurs at a substantially higher rate than the expected simple single hydrogen abstraction [349]:

Diazene formation requires the removal of hydrogen atoms from opposite ends of the hydrazine molecule, which at first glance seems very unlikely, in particular because the neighboring hydrogen atoms in an amino group are only 0.157 nm apart (which is very close to the 0.152 nm in the water molecule), whereas two hydrogen atoms at opposite ends of the hydrazine molecule are at least 0.22 nm apart. One way to test this theory was to use UDMH or MMH in place of hydrazine. When UDMH was reacted with atomic oxygen under the same conditions, no dimethylaminonitrene  $\text{N}-\text{N}(\text{CH}_3)_2$  radicals or products of possible rearrangement, such as azomethane,  $\text{CH}_3\text{N}=\text{NCH}_3$ , were observed. Instead, only some  $\text{HN}^\bullet\text{N}(\text{CH}_3)_2$  was identified by the mass spectrometer, which indicated that the hydrogen abstraction reaction remained at this initial step of reaction, rather than proceed further and result in abstraction of both hydrogens from the same nitrogen atom. Further evidence became available from the crossed molecular beam bombardment of MMH with oxygen atoms. In these tests the ion current at a mass-to-charge ratio ( $m/e$ ) of 44, corresponding to  $\text{HNNCH}_3^+$ , increased drastically. Some radicals ( $\text{HN}^\bullet\text{NHCH}_3$  or  $\text{H}_2\text{NN}^\bullet\text{CH}_3$ ) formed by the abstraction of a single hydrogen atom were also observed at  $m/e$  45. In previous tests with UDMH decomposition by hydrogen atoms, the compound with  $m/e$  44 could be identified as  $\text{HN}=\text{NCH}_3$  and exhibited a surprising stability, in that it could be frozen out from the reacting mixture on a cold finger and would reappear when the condensate thawed. Based on the appearance potential of  $\text{HNNHCH}_3^+$  from MMH, a bond dissociation energy  $D(\text{H}-\text{NHNHCH}_3)$  was calculated as  $276 \pm 21 \text{ J/mol} = 66 \pm 5 \text{ kcal/mol}$ . This was somewhat lower than the hydrogen bond dissociation energy in hydrazine itself,  $D(\text{H}-\text{NHNH}_2) = 318 \pm 21 \text{ J/mol} = 76 \pm 5 \text{ kcal/mol}$ . Bond energies were already discussed in Section 2.3.3. In additional tests with oxygen atoms generated from the reaction  $\text{N} + \text{NO} \rightarrow \text{N}_2 + \text{O}$  rather than by glow discharge in  $\text{O}_2$  gas, it could be proved that the reactive species is indeed  $\text{O}^\bullet$  and not excited atomic or molecular states of oxygen.

A discharge flow system with two independently movable reactant inlet tubes coupled to a time-of-flight (TOF) mass spectrometer was used to study the formation and

destruction of NO in the H-N-O system, as well as with isotope labeling of the reactants [543]. The formation of nitric oxide in the reaction of oxygen atoms with hydrazine is likely to proceed through fission of the diazene N=N bond, since the principal step

preserves the hydrazine N—N bond [544]. The buildup of NO may also be related to the formation of  $\bullet\text{NH}_2$  radicals, which could be observed in large amounts in the  $\text{O}^\bullet + \text{N}_2\text{H}_4$  reaction. When this reaction was carried out in the presence of an excess of  $^{15}\text{NO}$  and the reaction products analyzed in the mass spectrometer, an increase of  $m/e$  29 ( $^{14}\text{N}^{15}\text{N}$ ) and a decrease of  $m/e$  28 ( $^{14}\text{N}^{14}\text{N}$ ) could be observed. This can be explained by the simultaneous reactions

In addition, a significant increase at  $m/e$  45 was observed that is due to nitrosamine  $\text{H}_2^{14}\text{N}^{15}\text{NO}$ . The weak peak at  $m/e$  44 ( $\text{H}_2^{14}\text{N}^{14}\text{NO}$ ) disappeared after  $^{15}\text{NO}$  addition. This was the first conclusive evidence that  $\text{H}_2\text{NNO}$  is an intermediate product in the combustion of hydrazine.

### 3.1.1.7 Emission Spectra of Reaction Products of Atomic Oxygen with Hydrazines

In low Earth orbits, reactions of atomic oxygen (or hydroxyl radicals) with hydrazine vapors oozing from a thruster during evaporation of the dribble volume can cause chemiluminescence and interfere with sensitive optical systems on observation satellites. Similar chemiluminescence can be observed in the contrails of spacecraft re-entering the atmosphere destructively or destroyed on purpose to prevent spread of contamination if they have unused propellant on board. For this reason, reactions of atomic species with hydrazine vapors have been thoroughly investigated. Ground-state atomic oxygen  $\text{O}(^3\text{P})$  makes up 70% of the atmosphere at 300 km. Under conditions in orbit, the collision energy is increased by the orbital speed of the spacecraft colliding with a thermal cloud of atomic oxygen with Maxwellian energy distributions, causing surface glow of adsorbed propellant vapors.

The free radicals formed by the interaction of atomic oxygen (or hydrogen) with hydrazine or ammonia have been identified by emission spectroscopy [545]. The atomic gases were generated in a glow discharge and reacted with hydrazine vapor at a pressure of 133 kPa (1 mm Hg). The main emissions observed with  $\text{O}^\bullet + \text{N}_2\text{H}_4$  were those of  $\text{NH}_2$ ,  $\text{NH}$ ,  $\text{OH}$ , and  $\text{NO}$ . All four emission bands were very intense, and no undecomposed hydrazine or ammonia was found in the condensate. The luminous zone of the  $\text{O}^\bullet + \text{N}_2\text{H}_4$  atomic flame is very narrow compared with that of other atomic flames at the same pressure. This showed that the reaction between  $\text{O}^\bullet$  and  $\text{N}_2\text{H}_4$

proceeded very quickly. When ammonia was substituted for hydrazine, only the NH band was observed as a very weak emission, and 90% of the ammonia was destroyed. Corresponding experiments with atomic hydrogen were discussed in Section 4.7.4.1.

One of the reaction products of hydrazine with atomic oxygen is nitric oxide NO. NO is formed as an intermediate in the reaction, and some may persist and show up as a byproduct of this reaction [546, 547]. Spectroscopic studies have focused on NO emission spectra from  $O^\bullet + N_2H_4$  flames at 0.46–4 Pa (3.5–30  $\mu\text{m}$  Hg) hydrazine or atomic oxygen partial pressure. This work is of particular interest in view of the possible application of hydrazine as an internal combustion engine or scramjet fuel, where NO would be an undesirable contaminant. Once the formation of NO in hydrazine flames is fully understood, corrective action can be taken in combustion engines to avoid its formation by changing the mixture ratio or going to staged combustion. The intensity of the NO bands (due to the  $A^2\Sigma \rightarrow X^2\Pi$  transition) increased strongly by the addition of NO. This suggested that the excited NO was not a primary product of the reaction but rather became excited by energy transfer from another molecule, most likely active dinitrogen in an  $A^3\Sigma$  metastable state. The same dinitrogen was also shown to excite the 253.7-nm line if a trace of mercury vapor was added to the reaction mix. The formation and destruction of nitric oxide in  $O_2/NH_3$  and  $O_2/N_2H_4$  flames and the rate of the reaction

were measured directly for the first time [543]. This reaction is closely related to the decomposition of nitrosamine

postulated as an intermediate product in the combustion of hydrazine. For the first time nitrosamine could be identified as a reaction product of oxygen (atoms) and hydrazine by mass spectrometry [543]. The experimental setup was used to generate atomic species and radicals consisting of a flash-photolysis arrangement with a glow discharge system. Oxygen atoms were continuously generated in a microwave discharge and were present in excess in relation to the amino radicals produced by the photolysis of ammonia. To avoid radical-radical reactions and maintain isothermal conditions, the radicals were diluted with large quantities of inert gas. The decay of the amino radical concentration as a result of reaction with oxygen was measured by time-resolved absorption spectrometry at 597.9 and 516.6 nm. No decay was observed in the absence of oxygen atoms at  $10^{-11}$  mol amino radicals/ $\text{cm}^3$ . With an excess of oxygen atoms, the decay of  $NH_2$  concentration was strictly first order, and the rate constant was  $k = 2.1 \times 10^{12} \text{ cm}^3 \text{ mol}^{-1} \text{ s}^{-1}$  at 298 K. The reaction can proceed through

or

Data on the reaction of  $\text{O}^\bullet$  with  $\text{NH}_3$  support the first path, but even with an optical path of 20 m, no definite absorption could be observed that could be attributed to  $\text{HNO}$ .

The large amount of energy released in the reaction

results in vibrationally excited water molecules that could be identified by IR emission bands. Other theoretically possible products of this reaction could be eliminated because no hydrogen atoms were found by electron spin resonance (ESR) spectroscopy:

Hydrazines will quench the atomic oxygen singlet  $\Sigma$  emission at 1270 nm [548]. Twenty-five different hydrazines were tested in this reaction, and the emission at 1270 nm was measured as a function of time. The quenching mechanism includes electron transfer, electronic  $\rightarrow$  vibrational transfer, and contact charge transfer. It has been suggested that it might be possible to detect hydrazine leakage from satellites in low orbits, where the natural atomic oxygen concentration is high enough ( $10^9$  atoms  $\bullet\text{O cm}^{-3}$ ) to cause chemiluminescence [549].

Not only collisions with atomic oxygen, but also  $\text{O}^+$  ions at suprathermal energies (4–50 eV) result in the chemiluminescence of hydrazine vapors [550, 551]. Collision energy cross sections were measured as a function of the collision energy, using a quadrupole mass spectrometer (QMS) with chopped beams. Emissions detected in the 250–850 nm range were  $\text{OHA}^2\Sigma^+ \rightarrow \text{X}^2\Pi$  at 306 nm and  $\text{NHA}^3\Pi_i \rightarrow \text{X}^3\Sigma^-$  at 336 nm. The OH emission intensity decreased with increasing collision energy, while the NH intensity increased with increasing collision energy. In addition to  $\text{O}^+$ , other ions ( $\text{Ar}^+$ ,  $\text{Kr}^+$ ,  $\text{CO}^+$ ,  $\text{CO}_2^+$ ) were also aimed at hydrazine vapor for comparison. The  $\text{O}^+/\text{N}_2\text{H}_4$  high-mass product reaction sections sum to 15–20 Å<sup>2</sup>.

Laboratory measurements of 1.5 to 5  $\mu\text{m}$  FTIR spectra from  $\bullet\text{O}$  flames with hydrazine, MMH, or UDMH identified several species, among them OH,  $\text{H}_2\text{O}$ , CO,  $\text{CO}_2$ , HNO,  $\text{H}_2\text{CO}$ . It was suggested that  $\bullet\text{O}$  reacts with methylhydrazine to form  $\text{H}_2\text{CO}$  and  $\text{N}_2\text{H}_4$ , which then decomposes through well-established channels. For additional publications on atomic oxygen-hydrazine reactions, see [544, 552–555], also on the use of ESR spectroscopy for the identification of intermediates.

The reactions between hydrazine and atomic oxygen and free hydroxyl radicals were studied under laboratory conditions. The gas phase kinetics of  $\text{O}(^3P)$  and OH reactions with  $\text{N}_2\text{H}_4$ ,  $\text{CH}_3\text{NHNH}_2$ , or  $(\text{CH}_3)_2\text{NNH}_2$  were studied in a discharge flow-tube apparatus [555, 556]. The reactions were studied in 267 Pa (2 mm Hg) of He dilution under pseudo-first-order conditions in the transient species concentration with a known

excess of hydrazine concentration. The steady-state concentration temporal profiles of the transient species were directly monitored by fluorescence techniques to deduce the absolute second-order reaction rate coefficients. The Arrhenius expression

$$k = (7.35 \pm 2.16) \times 10^{-13} \exp(640 \pm 60)/T \text{ cm}^3 \text{ mol}^{-1} \text{ s}^{-1}$$

in the temperature range 252–640 K was obtained for the reaction of  $\text{O}(^3P)$  with  $\text{N}_2\text{H}_4$ . The corresponding expression

$$k = (1.25 \pm 0.19) \times 10^{-11} \exp(315 \pm 55)/T \text{ cm}^3 \text{ mol}^{-1} \text{ s}^{-1}$$

in the range 232–374 K was determined for the  $^{\bullet}\text{OH}$  reaction. The total yield of  $\text{OH}(X^2\Pi)$  formation in the  $\text{O} + \text{N}_2\text{H}_4$  reaction of  $(0.15 \pm 0.05)$  at 298 K (of which ~50% was found to be produced hot with vibrational excitation up to the limit of reaction exothermicity) and the observed experimental kinetic trends suggested that the initial addition of  $\text{O}(^3P)$  and  $^{\bullet}\text{OH}$  to the hydrazine molecule followed by rapid dissociation to products is an important process step in the atmospheric degradation of hydrazine. In a later study [556] with direct laser-induced fluorescence monitoring of  $[\text{OH}]$  temporal profiles in a known excess of hydrazine yielded the following absolute second-order OH rate coefficient expression:

$$k_1 = (2.17 \pm 0.39) \times 10^{-11} \exp(160 \pm 30)/T \text{ cm}^3 \text{ mol}^{-1} \text{ s}^{-1},$$

for reactions with  $\text{N}_2\text{H}_4$  in the temperature range 232–637 K.

An ESR study of the reaction of atomic oxygen with hydrazine at 420 K, 0.7 mm Hg, and contact time of  $5 \times 10^{-3}$  s gave a rate constant of  $(3 \pm 0.8) \times 10^{12} \text{ cm}^3 \text{ mol}^{-1} \text{ s}^{-1}$  [557, 558]. The initial step is

followed by

Most publications on reactions of atomic oxygen with hydrazine deal with gas-phase reactions at very low pressures that do not involve solid surfaces. It should be mentioned that adsorbed molecular oxygen on a platinum single crystal (111) face is likely to dissociate into adsorbed atomic oxygen and react rapidly with hydrazine vapor [559].

### 3.1.1.8 Kinetics of Gas-Phase Reactions of Hydrazine with Hydroxyl Radicals and Ions

Besides  $\text{O}^{\bullet}$  atoms, hydroxyl radicals  $^{\bullet}\text{OH}$  are presumed to play an important role in hydrazine combustion. The reaction of  $^{\bullet}\text{OH}$  with  $\text{N}_2\text{H}_4$  could be studied individually by

the crossed molecular beam method [560]. Whereas the attack by  $\text{H}^\bullet$  or  $\text{O}^\bullet$  leaves the N—N bond of hydrazine intact, the reaction with  $\bullet\text{OH}$  proceeds mainly under fission of the N—N bond:

The identification of  $\text{NH}_2\text{O}$ , a little-known species, by mass spectrometry was difficult because its  $m/e$  coincides with that of hydrazine at 32. Its existence could be proved using OD instead of OH radicals, in which case the reaction proceeded as follows:

and the  $m/e$  of NHDO is distinctly different from that of undecomposed hydrazine.

A study of the action of hydroxyl radicals (Fenton reagent) on hydrazine in aqueous solution is described in Section 3.1.1.1 on the oxidation of hydrazine in solution, and, in addition, as a result of hydroxyl radicals formed by the radiolysis of water. Tetrazene and triazene are some of the species identified as intermediates in this reaction.

The temperature and concentration profiles of OH,  $\text{NH}_2$ ,  $\text{H}_2\text{O}$ ,  $\text{N}_2$ ,  $\text{O}_2$ , and NO across the reaction zone of oxygen-ammonia flames were measured for three different mixture ratios in premixed flames [561]. In addition to the reaction of hydroxyl radicals with hydrazine (or ammonia) and mass spectroscopic analysis of the reaction products in the gas phase [560], the reaction has also been investigated by ESR. The ESR spectrum is specific to the free electrons in free radicals, such as  $\bullet\text{OH}$  or  $\bullet\text{NH}_2$ . However, the accuracy with which spectra can be measured is inversely proportional to the lifetime of the free radicals. In one arrangement, the reactions of  $\bullet\text{OH}$  radicals with ammonia or hydrazine were studied in an isothermal flow reactor at pressures around 266 Pa (2 mmHg) with helium as carrier gas [562]. The fast reaction

has been used for generating hydroxyl radicals. Only small  $\bullet\text{OH}$  concentrations were used in order to avoid recombination with itself or uncontrolled wall reactions. The  $\bullet\text{OH} + \text{NH}_3$  or  $\bullet\text{OH} + \text{N}_2\text{H}_4$  mixtures were then flowed through the cavity of an ESR spectrometer. The flow rate and the ratio of reacting species could be varied to determine a time-resolved reaction profile. The reaction rate for  $\bullet\text{OH} + \text{NH}_3 \rightarrow \text{NH}_2 + \text{H}_2\text{O}$  was measured at 298–669 K and found to be  $k = (3.2 \pm 0.5) \times 10^{12} e^{(-920/T)} \text{ cm}^3 \text{ mol}^{-1} \text{ s}^{-1}$ . The reaction

was measured at ambient temperature (298 K) only, and a rate of  $k = (1.3 \pm 0.3) \times 10^{13} \text{ cm}^3 \text{ mol}^{-1} \text{ s}^{-1}$  was found. In the overall reaction,  $2.5 \bullet\text{OH}$  radicals were removed for every  $\text{N}_2\text{H}_4$  consumed, leading to  $\text{N}_2$  and  $\text{H}_2\text{O}$  as the main final products. The rate con-

stant measured in the gas phase is like that measured in solution ( $1.4 \times 10^{10} \text{ M}^{-1} \text{ s}^{-1} = 1.4 \times 10^{13} \text{ cm}^3 \text{ mol}^{-1} \text{ s}^{-1}$ ) [563]. Gas-phase reactions of  $\bullet\text{OH}$  with ammonia or hydrazine share some of the intermediates [564].

The reaction of  $\text{N}_2\text{H}_4$  with hydroxyl  $\bullet\text{OH}$  free radicals that gives  $\text{N}_2\text{H}_3$  as the major product has been investigated by quantum-chemical calculations [565]. The results showed that the hydrogen abstraction mechanism is more feasible than the substitution mechanism thermodynamically. The calculated rate constants agreed with the available experimental data. The calculated results showed that the variational effect is small at lower temperatures, while it becomes significant at higher temperatures. The calculated rate constants showed a negative temperature dependence at temperatures below 500 K, which was in accordance with reports that a slightly negative temperature dependence was found over the temperature range of 258–637 K.

Activation energies of reactions of hydrazine with  $\text{CH}_3$  and  $\text{OOH}$  radicals including hydrogen abstraction and substitution reactions were calculated using quantum-mechanical computational methods [566]. The activation energies of hydrogen abstraction from  $\text{N}_2\text{H}_4$  by  $\text{CH}_3$  and  $\text{OOH}$  radicals were 21.89 and 25.24 kJ/mol, respectively. Generally, activation energies of the hydrogen abstractions were smaller than those of substitution reactions. The rate constants of the reactions were calculated using the transition state theory in a temperature range of 200–2500 K. The rate constants of hydrogen abstraction from hydrazine by  $\text{CH}_3$  and  $\text{OOH}$  radicals were  $3.47 \times 10^{-13}$  and  $6.79 \times 10^{-13} \text{ cm}^3 \text{ mol}^{-1} \text{ s}^{-1}$ , respectively, at 298 K. Hydrogen abstractions were exothermic, while almost all the substitution reactions were endothermic. One of the  $\text{NH}_2$  groups of  $\text{N}_2\text{H}_4$  can be replaced with  $\text{CH}_3$  or  $\text{OOH}$  radicals, which leads to  $\text{H}_2\text{NCH}_3$  or  $\text{H}_2\text{NOOH}$  products, respectively. The formation of  $\text{H}_2\text{NCH}_3$  was exothermic, while the formation of  $\text{H}_2\text{NOOH}$  was an endothermic reaction.

The energy profile of reactions of  $\text{H}_2\text{NN}\bullet\text{H}$  and  $\text{H}_2\text{NNH}_2^{\bullet+}$  with  $\text{HO}\bullet$  in the gas phase was studied using a modified *ab initio* method [567]. During the attack of  $\text{HO}\bullet$  on  $\text{H}_2\text{NNH}_3^+$  in the gas phase, the rate of formation of  $\text{H}_2\text{NNH}_2^{\bullet+}$  by H abstraction from the  $\text{NH}_3^+$  end of the molecule has a very low activation energy and is preferred over H abstraction from the  $-\text{NH}_2$  end. Most redox reactions of hydrazine in the liquid phase in the alkaline state involve hydroxyl anions  $\text{HO}^-$ . Comparatively little is known about reactions of hydrazine with hydroxyl ions in the gas phase. The energy potentials of 40 possible reactions in the presence of  $\text{HO}^-$  were calculated using a semi-empirical MNDO method and used to characterize most likely (least resistance) reaction paths of  $\text{HO}^-$  with  $\text{N}_2\text{H}_4$  vapor in the gas phase [568].

The low-pressure, vapor-phase reaction of hydrogen peroxide with hydrazine hydrate probably involves the intermediate formation of hydroxyl radicals formed by the decomposition of hydrogen peroxide [569]. At higher pressures this reaction would result in ignition.

The reaction mechanism of the  $\text{N}_2\text{H}_4 + \bullet\text{OH}$  reaction was examined by *ab initio* calculations for a wide range of conditions (i.e.,  $T = 200\text{--}3000 \text{ K}$  and  $P = 1\text{--}$

7600 mmHg) [570]. The kinetic rate model included corrections of the hindered internal rotor and tunneling effects. The calculated rate constants were in agreement with the latest experimental data [556], which helped to resolve the discrepancy between the previous experimental and theoretical studies. The reaction mechanism was revealed as follows: **(1)** the H-abstraction channel is more thermodynamically favorable than the OH-substitution mechanism; **(2)** non-Arrhenius behaviors and slightly positive pressure-dependence at low temperature ( $T = 500\text{ K}$ ) of the rate coefficients are observed; and **(3)** the hindered internal rotor treatment plays a substantial role in obtaining the reliable rate constants.

### 3.1.1.9 Kinetics of Gas-Phase Reactions of Hydrazine with Ozone

Hydrazine vapors released in the high atmosphere or stratosphere are surrounded by ozone, resulting in the rapid destruction of the hydrazine. Ozonizers have been used for chemiluminescence detection of hydrazine and nitrogen oxides in the effluent of gas chromatographs. The kinetics of the reactions of hydrazines with ozone are difficult to separate from the previously discussed reactions with atomic oxygen. Quite often atomic oxygen is the first product of ozone decomposition, and from then on the kinetics are the same as discussed previously. The current section would therefore only have to deal with the initiation steps.

The reactions of ozone with hydrazines are of practical interest: They take place in the atmosphere following the inadvertent release of hydrazine vapors in the atmosphere (Section 3.1.1.7). Ozonization is an attractive method for the disposal of unwanted hydrazines (Section 7.12.1.3). Ozone chemiluminescence is used in hydrazine analyzers (Section 3.6.11.5). Ozone is a convenient source of atomic oxygen for kinetic studies (*vide supra*). The current section deals with the kinetics of those reactions.

The homogeneous gas-phase reaction of hydrazine with ozone in air at atmospheric pressure is a convenient source for hydroxyl radicals [571]. The hydroxyl radicals can then be characterized by reactions with organic compounds for which rate constants were already known (based on the use of different hydroxyl generation methods). This reaction will most likely precede ignition when hydrazine is burned in ozone.

Hydrazine that has escaped to the high atmosphere where it is close to the ozonosphere is expected to be rapidly oxidized to nitrogen and water. Measurements were made of the reactions between ozone and hydrazine, MMH, and UDMH [572]. Measurements were carried out at room temperature, under pseudo-first-order conditions (hydrazines in excess), in a flow system designed to minimize diffusion limitations and wall reactions. Second-order rate constants were measured for each of the reactions. The measured values of the rate constants for the reactions of ozone with  $\text{N}_2\text{H}_4$ , MMH, and UDMH were  $3.4 \pm 0.4 \times 10^{-15}$ ,  $4.5 \pm 0.5 \times 10^{-14}$ , and  $5.5 \pm 1.3 \times 10^{-14} \text{ cm}^3 \text{ molecule}^{-1} \text{ s}^{-1}$ , respectively. The reaction is chemiluminescent.

### 3.1.1.10 Hydrazine Reactions with Ozone in Aqueous Solutions

Modeling of the kinetics of hydrazine ozonolysis showed that fuel destruction rates were limited by the rate of ozone input [573]. Using a stopped-flow technique, it was shown that while overall, global destruction was rapid, observed “rate constants” were five to six orders of magnitude lower than the true kinetic rate constants ( $10^7$  to  $10^9 \text{ L mol}^{-1} \text{ min}^{-1}$ ). Initial mol ratios of fuel to ozone consumption were about two to five, and this ratio decreased to less than unity or even less than unity as the ozonolysis proceeded.

The oxidation of hydrazinium salts in solution by gaseous (dissolved) ozone proceeds independently of the anion (nitrate or sulfate) present. When oxidizing  $10^{-2} \text{ M}$  solutions of hydrazinium(1+) nitrate or hydrazinium(2+) sulfate with ozone, ammonium and nitrate ions were found in the reaction products [574]. The amount of  $\text{NH}_4^+$  and  $\text{NO}_3^-$  formed was proportional to the amount of ozone consumed. The pH also decreased due to the additional hydronium ions formed. In a first approximation, the stoichiometry of the reaction can be represented as

Surprisingly, hydrogen peroxide can be identified as an intermediate while the ozone oxidation and autooxidation of hydrazine is in progress. Hydrogen peroxide concentration reaches a stationary level and drops off as soon as all hydrazinium ions are consumed. At that point, hydrogen peroxide itself is oxidized by ozone to form water and oxygen. Hydrogen azide or nitrous acid could not be found as intermediates, since either one would be rapidly oxidized to nitrate under the conditions of the test. When hydrazine hydrate is oxidized with ozone, only traces of ammonia and nitrate ion are found, and the main products are nitrogen, oxygen, and water:

As previously in the oxidation of hydrazinium salts, hydrogen peroxide was again found as an intermediate in the solution.

The use of ozone for the destruction of hydrazine(s) in wastewater usually occurs in combination with UV illumination and/or catalysts [575]. See Section 7.12.1.3.

### 3.1.2 Heterogeneous Surface-Catalyzed Reactions

The heterogeneous oxidation of hydrazine vapor by oxygen and oxygen/ozone mixtures on  $\text{SiO}_2$  or  $\text{Al}_2\text{O}_3$  surfaces was studied at 173 to 193 K in a flow reactor [576]. The reaction was zero order at ~70% conversion, and the activation energy was 38 kJ/mol. The oxidation rate for the case of  $\text{O}_2$  is an order of magnitude slower than for the  $\text{O}_2/\text{O}_3$  mixture. The vapor-phase reaction of ozone and hydrazine is more of interest for atmospheric chemistry than a practical means of hydrazine disposal.

All discussion in this section has centered around homogeneous gas-phase reactions of oxygen species with hydrazines, often initiating reactions leading to ignition

and combustion. Heterogeneous catalytic ignition of oxygen/hydrazine mixtures is possible but has not been studied in detail. A study of model catalytic oxidation reactions of dioxygen with hydrogen, ammonia, and hydrazine on Rh(111) single crystal surfaces in comparison to Pt(111) was one step in this direction [577].

Studying the autoxidation of hydrazine or methylhydrazines in confined atmosphere chambers in the laboratory is difficult. Hydrazine and oxygen may permeate through thin plastic walls. Metal walls may catalyze autoxidation [578].

### 3.1.3 Catalytic Ignition of Oxygen-Hydrazine Reactions

It is known that activated charcoal wetted with hydrazine will inflame spontaneously as soon as air is admitted. Likewise, oxygen-saturated activated charcoal or graphite oxide will react spontaneously or even explosively with hydrazine vapor. Graphite oxide, also called graphitic oxide or graphitic acid, is a compound of carbon, oxygen, and hydrogen in variable ratios, obtained by treating graphite with strong oxidizers. The maximally oxidized bulk product is a yellow solid with a C:O ratio between 2.1 and 2.9, and it retains the layer structure of graphite but with a much larger and more irregular spacing. It is spontaneously reactive with hydrazine [579]. Graphene can be made by the reduction of graphite oxide monolayer films by hydrazine with annealing in argon/hydrogen and an almost intact carbon framework that allows efficient removal of functional groups. This reduction would have to be done in dilute aqueous solutions to prevent ignition.

### 3.1.4 Reactions of Hydrazine with Hydrogen Peroxide in Solution

Hydrazine reacts readily with hydrogen peroxide in aqueous solution to yield nitrogen and water. Reactions of hydrazine with hydrogen peroxide are of interest for several reasons: The combination of hydrogen peroxide with mixtures of hydrazine hydrate and methanol is hypergolic and was the first liquid rocket bipropellant to be used in a piloted rocket plane, the Me-163B. In more dilute solutions, hydrogen peroxide is used for the treatment of hydrazine-polluted wastewater (Section 4.6).

It was discovered that the oxidation of hydrazine with hydrogen peroxide in acidic solution resulted in the formation of hydrogen azide [580]. This discovery has spurred numerous other investigators in an effort to predict the reaction products as a function of the oxidizing agent used. Azide formation occurred only in acidic solution. Three distinct reactions could be identified:

For example, the first reaction occurs when the oxidizing agent is acidic iodate, neutral iodine, or alkaline cyanoferrate(III). The second reaction is approximated with

iron(3+) or manganate as the oxidizer. Many oxidants give both first and second reactions simultaneously. The third reaction occurs predominantly if hydrazine is oxidized in hot, concentrated sulfuric acid with hydrogen peroxide.

A study of the effect of concentration, pH, temperature, ionic strength, and surface area ratio on the uncatalyzed rate of reaction of hydrazine and hydrogen peroxide in dilute solutions showed that, for the concentration range studied, the uncatalyzed reaction proceeded at a very slow rate as a first-order reaction in both hydrazine or hydrogen peroxide [581]. The reaction rate was very slow below pH = 8 but rose sharply above pH 8, and the fastest rate was observed at pH 10. At higher pH values, it dropped off again. A mechanism involving hydrazinium salts and diazene was proposed to explain the pH dependence. In this study, neither hydrogen azide nor ammonia was found in the gaseous products or in solution, although they probably can form when more concentrated solutions are reacted at low pH. See also [582, 583].

Transition metal ions catalyze the reaction of hydrazine with hydrogen peroxide [584, 585]. The rate of the  $\text{H}_2\text{O}_2 + \text{N}_2\text{H}_4$  reaction as measured by the rate of nitrogen evolution was quite erratic. Using a solution that was 0.4 molar in hydrogen peroxide and 0.2 molar in hydrazine and a temperature of 298 K (25°C), the initial rate of the reaction varied from 0.6 to 0.8 mL/s. The reaction was found to be first order in peroxide and zero order in hydrazine. The rate of the reaction depended on the purity of the water that was used as solvent. The addition of very small amounts of ethylene diamine tetraacetic acid (EDTA), a metal ion complexing agent, completely suppressed the reaction [586].

A thorough investigation of copper(II) catalysis showed that the rate-determining step of the catalyzed reaction involves hydrogen peroxide and copper ion [587, 588]. Since copper(II) has been shown to react slowly with hydrogen peroxide, the copper ion is probably complexed with hydrazine. It is this complex that then reacts with hydrogen peroxide. The rate coefficient for the catalyzed reaction is seven orders of magnitude higher than that of the uncatalyzed reaction, indeed a very pronounced effect! This also illustrates the importance of working with pure reagents in hydrazine chemistry because trace amounts of contaminants, such as  $\text{Cu}^{2+}$ , can give drastically altered results. The following rate law has been proposed for this reaction:

$$\frac{d[\text{N}_2]}{dt} = \frac{k_1 K [\text{N}_2\text{H}_4] [\text{H}_2\text{O}_2] [\text{Cu}^{\text{II}}]_{\text{T}}}{1 + [\text{N}_2\text{H}_4]}$$

where  $[\text{Cu}^{\text{II}}]_{\text{T}}$  represents the total concentration of copper. The enthalpy of activation and the entropy of activation of this reaction between 288 and 308 K were  $24.3 \pm 0.8 \text{ kJ/mol}$  ( $5.8 \pm 0.2 \text{ kcal/mol}$ ) and  $117 \pm 4 \text{ J mol}^{-1} \text{ K}^{-1}$  ( $28 \pm 1 \text{ cal mol}^{-1} \text{ K}^{-1}$ ), respectively.

Copper ions are the most active catalysts in this reaction [589]. It was shown that the reaction involves both radical ( $\cdot\text{N}_2\text{H}_3$ ) and nonradical ( $\text{HN}=\text{NH}$ ) intermediates. Free-radical reactions are often characterized by one-half- and three-half-order kinetics, rarely integer-order kinetics [590]. It is assumed that Cu(II) is first reduced to Cu(I), which forms a complex with  $\text{N}_2\text{H}_4$  [591].

The decomposition of hydrazinium ion acidic solutions by hydrogen peroxide solutions in a temperature range of 323 to 353 K (50 to 80 °C) was examined as a method for decontamination of hydrazine-containing wastewater from a nuclear power plant [592]. The presence of copper(II) ions  $[\text{Cu}^{2+}]$  substantially increased the decomposition reaction rate of hydrazine. The decomposition reaction rate of hydrazine also increased with the increase of temperature and the solution pH. Even an excess of hydrogen peroxide could not decompose the hydrazine efficiently at lower pH. The study neglected the possible formation of azide in acidic solutions. The oxidation of hydrazine with hydrogen peroxide leads to diazene, which has found widespread application as a selective reducing agent in organic chemistry.

### 3.1.5 Reactions of Hydrazine with Carbon Oxides

#### 3.1.5.1 Reactions with Carbon Dioxide

Reactions of hydrazine with atmospheric carbon dioxide, mostly through negligence in incompletely closed storage containers, have been the cause of numerous contamination incidents because the carbazic acid formed as the first step in this reaction and its hydrazinium salt are very corrosive and form a series of corrosion product salts when in contact with metals in storage containers. Not all these complex metal salts are hydrazine-soluble, and some may precipitate and cause clogging of narrow passages in the propulsion systems. Other complex metal carbazate salts are soluble in hydrazine but precipitate where hydrazine evaporates, such as on valve seats or in injectors. Hydrazine can react with one or, in the presence of an excess of carbon dioxide, two molecules of  $\text{CO}_2$ , forming a monocarbazic acid (or its hydrazinium salt) or a dicarbazic acid (or its hydrazinium salts). Carbazic acid itself is not stable, but many of its salts are stable and well characterized.

The reaction of hydrazine and carbon dioxide, the anhydride of carbonic acid, does not lead to hydrazinium carbonate, as one would expect. Instead, if carbon dioxide is bubbled through anhydrous hydrazine, a syrupy material results that is not inclined to crystallize and does not behave like a salt at all. If an excess of carbon dioxide is passed into hydrazine hydrate, a sparingly soluble precipitate is obtained; this was assumed to be hydrazinocarboxylic acid, also called carbazic acid [593]:

Reacting dry ice under conditions of supercritical carbon dioxide with hydrazine in an autoclave at 353 K (80 °C) and 100 bar for 10 h resulted in a solid product that was recrystallized and characterized by XRD as a zwitterionic compound  $\text{H}_2\text{N}^+\text{NHCOO}^-$ , like hydrazinium carbazate [594].

Carbon dioxide sequestration from industrial exhaust stack gases would be one way to alleviate global warming due to carbon dioxide release into the atmosphere. Reversible carbon dioxide absorption in industry is usually done with low-volatility organic amines, mostly for  $\text{CO}_2$  removal from synthesis gas and natural gas. It is not

known why anyone would want to use the more expensive hydrazine hydrate for that purpose, but it appears that CO<sub>2</sub> absorption into hydrazine hydrate can be readily reversible and that CO<sub>2</sub> release from the saturated liquid can be achieved at lower temperatures than with aliphatic amines [595–597]. Reaction mechanisms involved in CO<sub>2</sub> absorption into hydrazine hydrate solutions were identified using <sup>1</sup>H, <sup>13</sup>C, and <sup>15</sup>N NMR spectroscopy and compared to predictions from first-principles quantum-mechanical calculations. Both hydrazine monocarbazate (NH<sub>2</sub>–NH–COO<sup>–</sup>) and hydrazine dicarbazate (<sup>–</sup>OOC–NH–NH–COO<sup>–</sup>) were found, with the latter becoming prevalent with increasing CO<sub>2</sub> loading.

Hydrazinium carboxylate in concentrated solutions acts as a low-molecular-mass gelator, which self-assembles and in doing so traps unreacted hydrazine. The properties and molecular structures of the gels were investigated by means of elemental analysis, DSC/TGA, heteronuclear (<sup>1</sup>H, <sup>15</sup>N, and <sup>13</sup>C) NMR spectroscopy, and cryo-immobilized high-resolution SEM [598].

If anhydrous hydrazine (25 mL in a dish with 16.3 cm<sup>2</sup> surface area) is left standing exposed to the atmosphere, rapid absorption of CO<sub>2</sub> will increase the CO<sub>2</sub> (carbazate) content to 30% within 4 d [241]. At the same time, water content increases to 50%. The initial rate of CO<sub>2</sub> absorption is 50 ppm/min. This fast rate of CO<sub>2</sub> absorption is the reason anhydrous hydrazine must be kept blanketed with nitrogen at all times and contact with air must be avoided if one wants to maintain a corrosion-free system.

### 3.1.5.2 Reactions with Carbon Monoxide

The reaction of hydrazine with carbon monoxide at high pressure (91 MPa) and 314–320 K in the presence of iron pentacarbonyl leads to semicarbazide [599, 600]:

1,2-Dihydro-*s*-tetrazin-3(4*H*)-one is formed as a byproduct. If the reaction time is extended, 4-amino-1,2,4,4*H*-triazole-3(2*H*)-one and 4-amino-1,2,4,4*H*-triazole are obtained as ultimate products [601].

### 3.1.6 Reactions of Hydrazine with Nitrogen Oxides

Hydrazine reacts with numerous other nitrogen compounds [602]. Because hydrazine is the hydronitrogen with the strongest reducing power, these reactions invariably result in the oxidation of hydrazine.

The gas-phase reaction of hydrazine with nitrogen oxides is of practical importance in NO<sub>x</sub> removal from stack gases of combustion power plants prior to discharge into the atmosphere. Hypergolic ignition of N<sub>2</sub>O<sub>4</sub> with several propellant hydrazines is key to one of the most important applications of hydrazine as a bipropellant fuel (to be presented in a future *Encyclopedia of Hypergolic Bipropellant Combinations*). Reactions of hydrazine with nitrite ion, nitrite esters, and occasionally also nitrate ion

sometimes result in the unwanted formation of azides. Many azides are explosive hazards.

In the presence of moisture, the reactions of hydrazine (hydrate) with nitrogen oxides often involve reactions of hydrazine with nitrous acid and nitric acid. The reaction of anhydrous hydrazine or methylhydrazines with concentrated WFNA or even red fuming nitric acid (RFNA) leads in most cases to spontaneous ignition. These combinations have thus been investigated as hypergolic rocket propellants. The noncombustion reaction product of hydrazine and RFNA in a rocket chamber typically formed during evaporation of the liquids retained in the dribble volume, has been analyzed by IR and visible and mass spectrometry and was found to consist of at least 95% hydrazinium nitrate [603]. There was no evidence of hydrazinium nitrite. It has also been suggested that the nonignition residues contain ammonium nitrate or nitramine [604].

### 3.1.7 Reactions of Hydrazine with Nitrogen Dioxide or Dinitrogen Tetroxide

The vapor-phase reactions of hydrazine(s) with nitrogen dioxide often precede the ignition of such gas mixtures. Some of those pre-ignition reactions will be discussed in Section 4.15.1.1.

For a long time, pure hydrazine itself was not used as a fuel in bipropellant combinations because it is not suitable as a regenerative coolant. The pre-ignition or partial noncombustion reactions of hydrazine and methylhydrazines with NTO have been extensively investigated in an effort to explain occasional hard starts, pressure spikes, or rocket engine explosions as a result of accumulation of unreacted propellants and their partial reaction products in injector passages or dead corners of the combustion chamber. This problem required investigations of hard start phenomena and the chemical reactions of NTO with hydrazines, both in the liquid and in the vapor state [605–609]. For instance, hydrazine vapor and nitric acid vapor will not ignite below a certain partial pressure. Instead, a deposit of explosive hydrazinium nitrate will accumulate in the chamber. The same thing occurs after the propellant valves have closed and the combustion has ceased, when the propellants in the hold-up volume (“dribble volume”) between the valve and the injectors slowly evaporate. Reactions of hydrazine(s) with NTO and nitrogen dioxide leading to ignition will be discussed in a future *Encyclopedia of Hypergolic Bipropellant Combinations*, in the chapter “Hypergolic Combinations with Nitrogen Oxides.” IR spectra taken during the thawing of a mixture of  $\text{N}_2\text{O}_4$  and  $\text{N}_2\text{H}_4$  condensed on a sodium chloride window cooled to 77 K showed that all of the original material had reacted by the time the sample reached 163 K, whereas an exotherm in the DTA experiments was not observed until a temperature of 215 K was reached [610].

Another potential problem situation is the slow back-leakage of oxidizer through check valves into the helium pressurant of bipropellant rocket systems. The permeability of  $\text{NO}_2$  vapors through Teflon valve seats is relatively high. Since in some space-

craft designs fuel and oxidant share the pressurant helium supply, premature reaction may occur in the lines leading from the pressurant to the propellant tanks. This mechanism was suspected in the loss of the Mars OBSERVER space probe in 1993. Although that space probe used NTO and MMH, similar problems might occur in NTO/N<sub>2</sub>H<sub>4</sub> systems. Learning from the Mars OBSERVER fiasco, later space probes had separate oxidizer and fuel pressurant gas tanks.

The non-ignition reaction products of hydrazine and NTO contain hydrazinium(1+) nitrate (HN) [608, 611, 612] or hydrazinium azide [613, 614], as shown by IR analysis and comparisons of the spectra with authentic samples. A free-radical mechanism has been proposed to explain the other reaction products in addition to hydrazinium nitrate, namely, water, nitrogen, nitric oxide, nitrous oxide, and ammonia. An intermediate nitrosamine ONNH<sub>2</sub> has been postulated, but nitrosamine could not be detected because it is very unstable.

### 3.1.8 Reactions of Hydrazine with Nitrate Ion

The reduction of nitrate ion to nitrite ion by hydrazine in alkaline solution constitutes an important step in the analysis of atmospheric nitrogen oxides by wet microanalytical methods. The reduction of nitrate to nitrite ion in alkaline aqueous solutions in the presence of Cu<sup>2+</sup> and Zn<sup>2+</sup> catalysts is also used for the determination of trace nitrate in surface waters, sea water, or drinking water at concentrations below 10 mg nitrogen/m<sup>3</sup>. Following the reduction of nitrate, the nitrite is determined by using spectrophotometric sensitive reagents such as sulfanilic acid with *N*-(1-naphthyl)ethylenediamine (Saltzman reagent), *p*-amino acetophenone with azulene, or 8-anilino-1-naphthalene sulfonic acid (ANSA). The addition of a trace of copper(II) sulfate accelerates the reduction of nitrate.

The reaction of hydrazinium ions with nitrate ions limits the storage stability of aqueous hydrazinium nitrate solutions [615]. Azide formation is highly undesirable. Procurement specifications for hydrazinium nitrate solutions must include a maximum tolerable limit of azide.

### 3.1.9 Reactions of Hydrazine with Halogens and Hypochlorite

The most common method for the destruction of unwanted hydrazine, as well as hydrazine decontamination in diluted hydrazine spills, is by reaction with sodium hypochlorite (chlorine bleach) or calcium hypochlorite (HTH<sup>®</sup>, a swimming pool sanitizing agent) in dilute solutions. This method can also be used to decontaminate MMH or UDMH but may result in the formation of traces of chloroform, an unwanted, even more persistent contaminant. Reactions of hydrazine with halogens and interhalogens result in the formation of nitrogen and hydrogen halides [616].

The hypergolic combination of liquid fluorine with hydrazine has been evaluated as propellant for upper stages. This application will be described in a future *Ency-*

*lopedia of Hypergolic Bipropellant Combinations*, in the chapter “Hypergolic Combinations with Fluorine.” The kinetics of the reaction of fluorine with hydrazine may involve hydrogen abstraction as the first step of the reaction. The low-pressure gas-phase reaction between  $\text{N}_2\text{H}_4$  and F atoms is predicted to have three possible reaction channels. Calculated results revealed that the first two primary channels

are equivalent and occur synchronously via the formation of a pre-reaction complex rather than via direct H abstraction [617].

### 3.1.10 Reactions of Hydrazine with Boron Compounds

Hundreds of reactions of hydrazine(s) with boron halogenides, hydrides, alkali metal boranates, and alkyl boron derivatives have been reported. Many hydrazine and boron compounds have been tested as rocket propellant ingredients, mostly for solid propellants. The reason for the versatility of hydrazine-boron interactions is the charge-transfer bond formed in many of these compounds between the free electron pairs of the nitrogen atoms in hydrazine with the electron-deficient boron atom. The information is arranged in sequence by the number of boron atoms involved. Boron hydrides (boranes) are discussed first, followed by alkyl boron compounds, boron halogenides, and boric acid and boric acid esters.

Many boron compounds form Lewis-type adducts with hydrazine and hydrazine derivatives. Many boron compounds crystallize with excess molecules of hydrazine as solvate.

Hydrazinoborane, diborylhydrazine,  $\text{H}_2\text{B}-\text{NH}-\text{NH}-\text{BH}_2$  can be prepared by pyrolysis of a hydrazine-diborane adduct [618]. Alkylated homologs can be prepared by the treatment of tetraalkyldiboranes with hydrazine at 373–423 K [619].

Hydrazine and diborane react hypergolically with a hot flame:

The flame reaction has actively been investigated as a rocket propellant combination. The flame speed of the stoichiometric mixture on a 28-mm burner was 5 m/s [620, 621]. The premixed  $\text{N}_2\text{H}_4/\text{B}_2\text{H}_6$  flame could be stabilized only at pressures below 6.6 kPa (50 mm Hg) because solid adducts often clogged the orifices at higher mixing pressures [622].

Hydrazine borine  $\text{BH}_3 \cdot \text{N}_2\text{H}_4$  can be obtained by reacting dihydrazinium(1+) sulfate  $(\text{N}_2\text{H}_5)_2\text{SO}_4$  with lithium borohydride in ether or, even better, with sodium borohydride in dioxane [618]. The reaction between hydrazinium sulfate and sodium borohydride is very slow and requires 5–15 h at 300 K. The product crystallizes from the dioxane filtrate. Its precipitation can be accelerated by adding petroleum ether, in which hydrazine borine is insoluble. The compound crystallizes in colorless columnar crys-

tals and melts at 334 K. It is soluble in water, alcohol, ether, hydrazine, and other polar solvents. It is stable in aqueous solution and will not decompose unless the solution is acidified below  $\text{pH} = 4$ .

Hydrazine bisborane can be prepared by the reaction of alkali metal borohydrides with hydrazinium salts [623, 624] or by the reaction of trimethylamine borane with hydrazine [625]. The reaction of hydrazine bisborane  $\text{H}_2\text{B}-\text{NH}-\text{NH}-\text{BH}_2$  with hydrazinium perchlorate gives complex salts of the  $\text{N}_2\text{H}_4\text{BH}_2\text{ClO}_4$  type, which can be used as rocket propellants [626].

Various adducts of hydrazine and alkali metal or aluminum borohydrides have been patented as rocket propellants, either as solids or as solutions in hydrazine. Adducts of aluminum, zirconium, or beryllium borohydride with hydrazine, UDMH, *O*-methyl hydroxylamine, or *N*-methoxy methylamine dissolved in ether are said to be hypergolic with nitrogen tetroxide [627].

Solutions of lithium borohydride in hydrazine lower its freezing point and increase the specific impulse when burned with oxygen as a rocket propellant [628]. Thus, solutions with 5.25, 6.1, 12.25, 13.25, or 15% by weight lithium borohydride in hydrazine lower the freezing point to 250, 246, 229, 226, and 235 K, respectively. The specific impulse of hydrazine with oxygen can be increased from 270 to 300 s by the addition of lithium borohydride. In the absence of solvents such as ether or dioxane, hydrazinate adducts of the type  $\text{LiBH}_4 \bullet \text{N}_2\text{H}_4$  are obtained that are soluble in excess hydrazine and, when crystallized, can be used as a rocket propellant [629].

Lithium borohydride and aluminum borohydride form hydrazinates and *N,N*-dimethylhydrazinates with hydrazine or UDMH, which can be used as rocket fuels [630]. With lithium borohydride in ether, the following compounds were isolated:  $\text{LiBH}_4 \bullet \text{N}_2\text{H}_4$ ,  $\text{LiBH}_4 \bullet 2\text{N}_2\text{H}_4$ , and  $\text{LiBH}_4 \bullet \text{H}_2\text{NN}(\text{CH}_3)_2$ . The compounds are white crystals that can be handled under air without danger, even though they are very hygroscopic. In contrast, the hydrazinates of aluminum borohydride are very sensitive to oxygen and must be handled in an inert atmosphere. Aluminum borohydride accepts up to four hydrazine molecules as solvates:  $\text{Al}(\text{BH}_4)_3 \bullet 4\text{N}_2\text{H}_4$ . Solutions of hydrazinium decaboranate in hydrazine can be used as hypergolic fuels [631, 632].

One of the most unusual liquid rocket propellant combinations is that of hydrazine with pentaborane. On contact, the components react in a highly exothermic reaction, and a combustion-like reaction can be sustained in a rocket engine. The reaction leads to boron nitride and hydrogen:

The low molecular weight of the exhaust gases (mainly hydrogen) results in a very good specific impulse of this propellant combination, which will be further discussed in a future *Encyclopedia of Hypergolic Bipropellant Combinations* [633].

### 3.2 Electrooxidation of Hydrazine in Solution

Electrooxidation of hydrazine in solution is a key step in using hydrazine hydrate solutions in air-fuel cells. Automobiles with air/hydrazine hydrate fuel cells would be a pollution-free mode of transportation. In the anodic oxidation of hydrazine in solution, the oxygen that would have evolved at the anode in plain (acidified) water does not evolve but is immediately desaturated by reaction with hydrazine. The electrooxidation of hydrazine is the basis of coulometric analysis of hydrazine and other electrochemical analysis methods (Section 3.6.10). A thorough discussion of the kinetics of electrooxidation and importance of electrode selection can be found in [634]. Practical applications of electrooxidation of hydrazine(s) are discussed in Section 3.6.15.12.

Hydrazine is an excellent solvent and can serve as the electrolyte for many reactions. Because anhydrous hydrazine is an electrolyte due to autodissociation, the electrooxidation of hydrazine in the absence of a solvent is possible. That method has been considered as a method for the controlled release of gases for micropropulsion in satellites.

The oxidation of hydrazine in acid and alkaline aqueous media has been examined. It was concluded that the oxidation of hydrazine occurs not primarily via a hydrogen oxidation mechanism, as was previously suggested, but via a sequential oxidation of radicals (intermediates) derivable from hydrazine. It was also concluded that electrode surface characteristics affect the potential of oxidation, while the rest potential is controlled by the subsequent formation of radicals [515].

Hydrazine can be oxidized by electrooxidation in liquid ammonia as the electrolyte and solvent. Potential sweep investigations of the electrochemical oxidation of hydrazine on platinum in liquid ammonia electrolytes yielded current-potential curves that depended markedly on the nature of the electrolyte anion present [635]. These anion effects were interpreted in terms of the principle of soft and hard acids and bases and specific adsorption at the electrode. Low-temperature studies showed that hydrazine can be electrochemically oxidized in liquid ammonia at 213 K (60 °C), demonstrating the high reactivity of this fuel. The oxidation of hydrazine on platinum appears to be a diffusion-controlled, highly irreversible reaction.

It was stated that the amount of nitrogen released on oxidation of 0.5 M  $\text{N}_2\text{H}_4$  in 5 M KOH at 293 K on platinum electrodes corresponded to the quantity calculated from the number of coulombs passed through the system [636]. Using palladium-black coated electrodes, it is possible to electrolyze hydrazine in alkaline solution per

without the chemical decomposition of hydrazine [637]. The anode gas thus obtained is mostly nitrogen free from hydrogen.

It was suggested that the hydrazine electrode is essentially a low-pressure hydrogen electrode, and it was verified that the hydrogen pressure is a function of the hydroxide ion concentration since it is roughly proportional to its third power [638]. It

was assumed that the hydrazine molecule was first adsorbed on the platinum electrode, where it underwent a decomposition to nitrogen and hydrogen.

The electrochemistry of hydrazine electrooxidation at platinum electrodes has been re-evaluated by an investigation using microelectrodes [639]. Platinum oxides remaining on the electrodes from preceding oxidative scans will facilitate hydrazine oxidation occurring at up to ca. 400 mV more cathodic potentials than at an oxide-free Pt electrode. The observed voltammetry at oxidized or “activated” platinum electrodes was found to be a function of the immersion time (time elapsed since “activation”) and pH. Although hydrazine is known to react with bulk Pt oxide, the loss of activation with time was found to be independent of hydrazine concentration and was instead a function of pH and supporting electrolyte.

During a study of the effects of the supporting electrolyte on electro-catalytic oxidation of hydrazine hydrate on a platinum ultramicroelectrode, it was found that the  $H^+$  electric field generated during the catalytic process could partly hinder the reactants from participating in the catalytic reaction using low-concentration supporting electrolytes, which resulted in a final steady current value that was less than the theoretical value [640]. On the other hand, the supporting electrolyte has a regulatory effect on both concentrations of  $N_2H_4$  and  $N_2H_5^+$  involved in the catalytic reaction, which in turn affects the intensity of steady-state currents and the value of each steady-state current generated in the reaction. In this case, the effect of neutral salts did not change with concentration variations. By contrast, when different concentrations of sulfuric acid or sodium hydroxide are used as the electrolytes, the intensity of steady-state currents and the value of each steady-state current were mainly determined by the original and the subsequently produced  $H^+$  concentration around the electrode. This information assists in the choice of supporting electrolyte and catalytic potential in the determination of hydrazine concentrations by amperometric methods and in catalytic reactions with hydrazine hydrate as the reducing medium.

### 3.3 Nitride Formation with Metals

At very high temperatures, such as those occurring in hydrazine decomposition monopropellant reactors, nitride formation with structural metals may lead to premature degradation, embrittlement, and failure of structural elements such as catalyst bed retention screens, bed plates, injectors, nozzles, and chamber materials. Traces of carbon can aggravate the nitride formation. Metallurgists had to go through a long period of trial-and-error evaluation of candidate metals for hydrazine rocket engines and gas generators before alloys were found that could resist the harsh environment in hydrazine decomposition reactors. While metal nitriding is highly undesirable, nitriding of semiconductor elements under carefully controlled high-vacuum conditions has developed into a new application for ultra-high-purity hydrazine.

### 3.4 Reactions of Hydrazine with Organic Compounds

Reactions of hydrazine with organic compounds can be grouped into the following categories: hydrazination reactions, cyclization reactions, and hydrogenation reactions. Hydrazination reactions generally leave part of the molecule, maybe one  $\text{—NH}_2$  group, unreacted, and the products share many of their properties with hydrazine, including the ease of becoming oxidized. On cyclization, frequently as part of the formation of heterocyclic ring systems, the properties of hydrazine disappear altogether, and the products are frequently much more stable than hydrazine by itself [641]. In hydrogenation reactions, the hydrazine is consumed, and the hydrogen is transferred to carbon. Reactions of hydrazine with organic compounds leading to alkyl- or arylhydrazines will be discussed in the chapters “Alkylhydrazines,” “Methylhydrazine,” and “Dimethylhydrazines.” Many of the reactions discussed here, such as the reaction with acyl halides, are observed with alkylhydrazines (MMH, UDMH) and hydrazine alike [642].

Reactions of hydrazine with organic compounds serve as analytical methods for qualitative and quantitative analysis of hydrazine(s). Reactions of hydrazine with organic compounds can also be useful to trap hydrazine, to reduce its vapor pressure, and to convert it to less toxic compounds. Such reactions would be useful for wastewater and spill decontamination. A more detailed summary of reactions of hydrazine with organic compounds is published in [643].

### 3.5 Hydrazinium Salts

Hydrazine forms two types of salts with acids, giving either monoprotonated hydrazinium(1+) or diprotonated hydrazinium(2+) salts. In aqueous solutions, normally only the hydrazinium(1+) salts are formed with a variety of acids. Hydrazinium(2+) salts form only with strong acids and/or in anhydrous media. Summaries of the properties of hydrazinium salts are provided in [644, 645]. Hydrazinium salts are useful sources of nitrogen in gas generant formulations. Hydrazinium salts of oxidizing acids are described in more detail in *Encyclopedia of Oxidizers*, in chapter “Hydrazinium Salt Oxidizers.”

### 3.6 Analysis of Hydrazine

The analysis of hydrazines is of importance in the production, quality control, application, occupational hygiene, and environmental control of these compounds. For most applications, the analysis methods will have to be quantitative.

Several monographs and survey articles appeared several decades ago [646, 647] which make a separate chapter on hydrazine analytical methods in this book almost

unnecessary. One frequently cited reference on this subject is a very specific book on the determination of hydrazino-hydrazide groups [648]. One book on the analysis of rocket propellants contains several chapters on hydrazine analysis [649]. A study was published on new methods for the analysis of hydrazine compounds and the use of hydrazine as an analytical reagent [650]. A chapter in the *Encyclopedia of Industrial Chemical Analysis* [651] provides a summary of analysis methods for hydrazine. Both books and the encyclopedia chapter contain detailed cookbook-style instructions for analysis and are suitable for use in the laboratory, whereas the book at hand is not. The objective here is only to provide an overview of analytical methods. Previous summaries on analytical methods such as those published in [22] are repeated here only in abbreviated form. In many cases, the user will not be spared the arduous walk to the library if more detailed step-by-step instructions for hands-on analytical methods are required. Hydrazine can be used as a reductant and analytical reagent [652].

The objective here is to arrange this chapter on chemical analytical methods by the method used, rather than by the application. This arrangement of subject sections in a logical sequence is not always easy to carry out consistently because many good surveys have been published that reviewed several candidate analysis methods for a given application, such as the analysis of water in hydrazine [653], the analysis of hydrazine in boiler feedwater [654, 655], or the analysis of hydrazines in body tissues or body fluids [656]. The wide-ranging use of hydrazine derivatives in growth retardants, pesticides, and pharmaceuticals made it necessary to test many of these consumer products for hydrazine residues. In the wake of growing consumer concern over pesticide residues on fruits and vegetables, methods of conducting trace analyses for hydrazine derivatives have yielded important information that served as the basis of environmental policies. The former National Bureau of Standards has compiled a summary of recommended methods for the analysis of hydrazines on crops [657].

Frequently, analytical surveys are conducted to find suitable analysis methods for hydrazines under field conditions, such as traces of hydrazine in the air (Section 3.6.15.1) or water (Section 3.6.14.1). Also, hydrazine fuels ready for loading into a spacecraft or aircraft frequently must be analyzed in the field without the luxury of having a well-equipped chemical laboratory nearby. Such field analysis instruments must be self-contained, be rugged, and give fast, unambiguous, and reliable “yes” or “no” answers with regard to the acceptability of a fuel within a given specification limit. For instance, rapid analysis methods are being sought for the field (flight line) analysis of the H-70 fuel mixture (70% hydrazine, 30% water) [485]. See also [658].

### 3.6.1 Qualitative Analysis of Hydrazine

Qualitative tests frequently give only a “yes” or “no” answer to the question as to whether a given sample (air, water, solid) contains hydrazine or not. Not all qualitative tests are suitable for quantitation.

In addition to *p*-dimethylaminobenzaldehyde (PDAB), other aldehydes such as salicylaldehyde can be used not only for gravimetric analysis, but also for spot plate tests identifying hydrazine in small quantities [659, 660]. The condensation reaction of salicylaldehyde and hydrazine in a 2:1 molar ratio usually gives initially a mixture of the three geometrical isomers of salicylaldazine [661].

A test tube/spot plate test for hydrazine uses a cacotheline reagent in 7–12N sodium hydroxide [662]. It gives a blue color that is stable for 1 h. The sensitivity is approximately 2 µg/mL. A red addition product is formed by the reaction of hydrazine with glutaconaldehyde as spot plate reagent [663]. The color formation is specific to hydrazine with selenous acid and 1-naphthylamine [664–666]. One hundred and thirteen organic substances, including alkyl hydrazines, alkyl-, and arylhydrazides, did not interfere. Some of these color-forming ingredients can be packaged by adsorption on resin beads that can be stored as solids and are easy to add to the solution to be tested. The reduction of silver diammino hydroxide by hydrazine gives a black spot on a paper chromatogram, but it is not specific [667]. Other reducing agents will cause the same reaction.

Hydrazines and amines form intensely colored adducts (Meisenheimer complexes) with aromatic nitro compounds that may be suitable for qualitative detection of hydrazine, MMH, or UDMH [668]. Many amines give similar colors, with the colors ranging from yellow to purple to black. One of the nitro compounds recommended for this test is trinitrobenzene [669].

*peri*-Naphthindan-2,3,4-trione hydrate is a sensitive reagent for the detection of hydrazine in spot plate tests [670] as well as spectrophotometric quantitative analysis [671]. The compound becomes reduced to a purple conjugated diol. The detection limit is 0.3 µg.

Various chemicals, including PDAB, pH indicators, and potassium tetrachloroaurate (KAuCl<sub>4</sub>), were tested for the detection of hydrazine or MMH vapors [672]. These indicators have been tested for the detection of hydrazine under various conditions: pure liquid fuel, aqueous fuel solution, saline aqueous fuel solutions, vapor fuel, and 3-month shelf life study, which included UV exposure, temperature extremes, and normal storage conditions.

### 3.6.2 Specifications for Hydrazine

Propellant specifications are important in the procurement and quality control of hydrazines. The rationale in setting specification limits is to achieve reproducible performance of rocket propulsion systems by carefully controlling the purity of propellant hydrazines. It is obvious that there must be a compromise between the propellant purity that can be achieved at reasonable cost and the level of inevitable contamination that the propellant user gets away with without getting into serious trouble. Excessively tight specification limits will result in many rejected propellant batches and additional expense both to the user and the propellant manufacturer. Quite often

specification limits were set arbitrarily without enough prior statistical process control studies. Table 42 is a summary of MIL-SPEC propellant specifications relating to hydrazine. A similar evolution has taken place for MMH specifications.

**Table 42:** Military specifications for hydrazine.

| MIL-SPEC Number              | Date        | Reason for revision, changes made                                                                                                                         |
|------------------------------|-------------|-----------------------------------------------------------------------------------------------------------------------------------------------------------|
| MIL-H-45701 (ORD)            | 20 Mar 1959 |                                                                                                                                                           |
| MIL-P-26536A                 | 31 Jul 1959 |                                                                                                                                                           |
| MIL-P-26536B                 | 13 Mar 1964 |                                                                                                                                                           |
| MIL-P-26536C                 | 23 May 1969 | Raise $N_2H_4$ assay from 97.5 to 98% min; lower $H_2O$ from 2.5 to 1.5% max                                                                              |
| Suppl.Data Sheet             | 15 Jun 1972 | Raise $N_2H_4$ assay from 98 to 98.5% min; lower $H_2O$ from 1.5 to 1.0% max; add particulate, Cl, Fe, NVR, $CO_2$ , organics limits                      |
| Amendment 1 (1 page)         | 25 Jul 1974 | Introduce new monopropellant grade with aniline limit of 0.5% max                                                                                         |
| Amendment 2                  | 1 Feb 1982  | Introduce new high-purity grade with aniline limit of 50 ppm max, NVR of 10 ppm max and $CO_2$ of 30 ppm max                                              |
| MIL-P-26536D (27 pp.)        | 27 Jul 1987 | Lower high-purity grade $NH_3$ from 0.4 to 0.3% max                                                                                                       |
| Amendment 1                  | 5 Jun 1995  | Specify range of $H_2O$ from 0.5 min to 1.0% max                                                                                                          |
| MIL-PRF-26536E-BASE (23 pp.) | 24 Sep 1997 |                                                                                                                                                           |
| Amendment 1                  | 10 Jan 2000 | Delete the minimum of 0.5% $H_2O$ requirement                                                                                                             |
| MIL-PRF-26536F (36 pp.)      | 1 Apr 2011  |                                                                                                                                                           |
| MIL-PRF-26536G (33 pp.)      | 11 Jul 2017 | Eliminate provisions for standard grade hydrazine; specify carbonaceous material to include <b>all</b> organic materials that give an FID response in GC. |

These specifications are frequently updated, and the user is advised to check the most recent status of the specification in question. Collections of most of the military specifications MIL-SPECs (as well as some previous revisions) are now available on government and commercial web sites. It is of interest to follow the historical evolution of hydrazine propellant MIL-SPECs as they exist today (Table 43).

The first hydrazine specification ever issued, MPD-139C, dates to 3 February 1955 and required only 95% hydrazine and allowed up to 1.5% aniline and *n*-heptane [673]. The purity requirements for hydrazine became more severe as the adverse effects of typical contaminants on monopropellant decomposition catalysts became better understood. Most hydrazine decomposition catalysts are very sensitive to contaminants that may act as catalyst poisons. A significant amount of effort has thus been devoted to identifying catalyst poisons and establishing tolerable levels of carbon-containing contaminants.

A comparison of different hydrazine specifications, especially for use in small thrusters, showed that the non-volatile residue (NVR) tolerance in monopropellant-grade hydrazine needed to be tightened further to prevent flow blockage in capillary feed tubes [674]. Non-volatile residue levels of 50 ppm in monopropellant Amendment A-grade and 30 ppm in so-called VIKING-grade hydrazine may still be too much for delicate injector capillary tubes of 0.44 N catalytic or electrothermal thrusters. Since the NVR limit cannot be lowered below the detection limit of the analytical method used, 10 ppm will be a reasonable limit if extremely low NVR levels are required. A 1-L hydrazine sample will have to be evaporated for each NVR determination, making this analysis more expensive and time consuming. The MIL-PRF requirements for H-70, a 70% hydrazine/30% water fuel mix used in the F-16 EPU, are listed in Table 44 [675].

### 3.6.3 Gas Chromatographic Analysis Methods for Hydrazine

Chromatographic methods are only separation methods that facilitate the subsequent identification of analytes in a mixture of substances. Identification of the analyte is made by retention time and comparison to an authentic sample or by applying a secondary identification method (spectrophotometry, mass spectrometry) to the enriched spot or eluate.

Gas chromatography (GC) is the most versatile method for both quantitative and qualitative (quality control) analysis of hydrazines. Most hydrazines are of sufficient volatility to allow separation from each other and from other constituents. However, the tendency of most hydrazines to undergo thermal or catalytic decomposition severely limits the operating temperatures and the choice of materials in a GC system. GC is also used for the analysis of gaseous decomposition products of hydrazine. Most GC applications use a liquid stationary phase, and the exact abbreviation of this would be GLC. Suffice it here to say that GC and GLC are intended to serve as abbreviations for the same analytical methods.

Water, MMH, and hydrazine were nicely separated at 383 K on a 1/4-in.-diameter  $\times$  6-ft.-long column filled with 10% Dowfax 9N9 on 60-80-mesh Teflon-6 [676, 677]. The fractogram also revealed traces of nitrogen and ammonia. For calibration purposes, response factors for water in hydrazine or MMH were determined by analyzing calibration mixtures of known composition. The reciprocal response ratio for water in hydrazine remained fairly constant (1.05) in the range 10–50% H<sub>2</sub>O. Likewise, it remained constant (1.15–1.20) for mixtures with 16–72% H<sub>2</sub>O in MMH. The column did not give satisfactory separation of UDMH from water in any of these mixtures and showed no loss of separating power after 200 injections. The addition of 1% sodium hydroxide to the stationary phase did not improve hydrazine separation, and better results were achieved in columns without NaOH.

The gas chromatography analysis method for hydrazine specified in MIL-PRF-26536G uses a 60- or 30-m  $\times$  0.53-mm, 1- $\mu$ m, DB-WAX capillary column, a thermal conductivity detector, with a split injector and an ultra-inert, deactivated, glass wool

Table 43: Historical evolution of specification limits for anhydrous hydrazine.

| Specification (Date)            | MIL-P-265361B (13 Mar 1964) | MIL-P-26536C (23 Mar 1969) | MIL-P-26536C Amendment 1 (25 Jul 1974) | MIL-P-26536C Amendment 2 (1 Feb 1982) | MIL-P-26536D (27 Jul 1987) | MIL-P-26536D Amendment 1 (5 Jun 1995) | MIL-PRF-26536E <sup>c</sup> Amendment 1 (10 Jan 2000) | MIL-PRF-26536G (11 Jul 2017) |

| Other volatile carbonaceous material (total as either MMH or UDMH/alcohol, % by weight) | 0.02 max   | GC                                                          |

packed split liner with dual temperature programming at two different rates, 10°/min between ambient and 100 °C and 20°/min between 100 and 185 °C.

For the analysis of water and ammonia in the H-70 fuel blend, a 3.17-mm × 0.61-m (0.125-in. × 2-ft.) column packed with 10% polyethylene glycol on 60- to 80-mesh Fluoropak was at one time recommended [678]. In calculating the results, corrections must be made for aniline that hangs up in the column. Aniline is determined separately by a spectrophotometric method. As an alternative to the spectrophotometric method, aniline in H-70 can also be analyzed by GC, using a 1.7% Amine 220/34% Apiezon L on 60–80 mesh silanized diatomaceous earth columns. With a GC-FID (flame ionization detector), the peak area must be calibrated from a known standard since water does not show in the FID. A later revision of the MIL PRF procedure specified a 60-m × 0.53-mm, 1-μm film thickness Agilent DB-WAX capillary column, a TCD, with a split injector and a glass wool packed split liner [675].

Three different columns – polyphenyleneoxide = Porapak Q; 20% loading of a mixture of 72% diethanolamine, 18% lauryl alcohol, 10% sodium iodide on Chromosorb W 80–100; 9% Carbowax MOA on Fluoropak – were tested for the separation of water, hydrazine, and its decomposition products [679]. Hydrogen in the mixture was determined in a separate injection with nitrogen as carrier gas and vice versa, requiring repeated injections of the same sample.

A review of existing methods for determining hydrazine and its short-alkyl and acyl derivatives with the use of different types of chromatography examined the selectivity and sensitivity of many different methods [680, 681]. Possible ways to increase the sensitivity of hydrazine determination were suggested and evaluated against examples of analyses of real samples.

### 3.6.3.1 GC Analysis Without Prior Derivatization

Improved separation of all three hydrazines and water was achieved using a stationary phase that is chemically similar to hydrazine [682]. In this case, 2-hydrazinopyridine, a polar liquid of low volatility, was used as the stationary phase in 10% concentration on Fluoropak 80. An attractive feature of the fractogram of a synthetic blend consisting of 27.9%  $\text{N}_2\text{H}_4$ , 27.9% MMH, 22.2% UDMH, and 21.9%  $\text{H}_2\text{O}$  depicted in [682] is the symmetry of the peaks, devoid of the tailing that is so characteristic (and disturbing) of  $\text{H}_2\text{O}$  and  $\text{N}_2\text{H}_4$  on other polar stationary phases. The constituents elute in the sequence UDMH,  $\text{H}_2\text{O}$ , MMH, and  $\text{N}_2\text{H}_4$ . 2-Hydrazinopyridine is strongly alkaline and will rapidly absorb  $\text{CO}_2$  from the air if the column is left open to the atmosphere. The column had to be stored tightly sealed while not in use. Even if kept in the GC under a flow of helium, the columns were operable for only 10 d. Significant vaporization losses ("bleeding") of the stationary phase occurred if the column was heated above 353 K.

Apparently some Third World countries in their quest for UDMH resorted to the direct methylation of hydrazine with dimethyl sulfate and obtained mixtures containing four methylated derivatives of hydrazine: MMH, UDMH, SDMH, and trimethylhydrazine, with some unreacted hydrazine and water that needed to be analyzed by GC [683]. Several columns with different stationary phases under different experimental conditions (temperature ramping, carrier gas flow, split/splitless injection) were used, but clearly resolved peaks of proper peak shape and integration could not be obtained.

GC analysis of water in hydrazine should be a fairly simple, straightforward procedure [684]. A packed column used for hydrazine analysis was replaced by a capillary column with improved results [269]. See also [685].

### 3.6.3.2 GC Analysis of Impurities in Hydrazine

Several attempts have failed so far to identify a column stationary phase/packing material that separates all contaminants commonly found in hydrazine equally well. Although satisfactory columns are available for MMH or UDMH, none was capable of simultaneously separating carbon dioxide, ammonia, water, MMH, UDMH, and 2-propanol (isopropanol = IPA) from the hydrazine. Normally, propellant-grade hydrazine contains only water, aniline, ammonia, and carbon dioxide. Sometimes MMH, UDMH, and IPA are accidentally introduced by careless transfer, storage, and cleaning procedures. A dual-column technique using three separate columns, namely, a 1-m  $\times$  6-mm 33% Carbowax 400 (PEG 400) on 90-100-mesh Anakron AB column (Column A), a 1.8-m  $\times$  6-mm 10% Dowfax 9N9 on 60-80-mesh TeeSix (Analabs) (Column B), and a 1.8-m  $\times$  6-mm 50-80-mesh Porapak PS column (Column C) was developed to achieve complete separation [686]. Column A did not separate UDMH/IPA or water/MMH. Column B did not separate water/UDMH or MMH/IPA. When A and B were used in combination, UDMH and IPA were still not quite separated. When combining columns B and C, six well-resolved peaks were obtained

in the fractogram of hydrazine spiked with all five contaminants, but this time hydrazine and MMH were not separated. With two separate injections on two different combinations of columns, a complete analysis could be achieved. Another alternative would have been to use a dual-column setup and backflush one of the unresolved pairs of peaks into another column for complete separation. At a column temperature of 373 K, aniline would always hang up in the column or at best elute as a very broad peak, causing gradual baseline shifts.

A column packing of 20% Ucon Oil 550X on Fluoropak-80 has been used for the analysis of small (0.5–2%) quantities of water in hydrazine [687, 688]. A ¼-in. × 10-ft. column at 376 K (103 °C) with 80-mL/min He at 172 kPa (25 psig) gave satisfactory separation of hydrazine from ammonia, methylamine, ethylamine, UDMH, and MMH.

### 3.6.3.3 GC Analysis Following Prior Derivatization

The detection limit for toxic or otherwise troublesome contaminants by GC has generally been improved by several orders of magnitude through the introduction of the FID. It is known that the FID is “blind” to hydrazine that combusts only to nitrogen and water. Alkylhydrazines give only a weak signal because they contain very little carbon. Sensitivity for the detection of hydrazine(s) by GC-FID can be improved by converting hydrazine(s) to volatile, thermally stable organic derivatives with high carbon (or even some halogen or silicon) content, such as hydrazones or azines. Similarly, the electron capture detector is very sensitive to halogen, and halogen-containing derivatizing agents improve the detection limit dramatically. The methods can also be adapted to analyze MMH or UDMH.

The following Table 45 summarizes some of the derivatizing agents used for GC and the types of derivatives formed. In search of additional derivatizing agents, it may be useful to scan the list of derivatizing agents used for high-performance (high-pressure) liquid chromatography (HPLC) (Section 3.6.4.2). Some derivatizing agents work equally well for GLC and HPLC. Many of the derivatizing agents that have been tested for the analysis of hydrazine derivatives (pharmaceuticals, growth retardants) can be applied to the analysis of hydrazine itself.

Details of GC analytical methods with derivatizing agents are described in [689]. The derivatizing agents used (in alphabetical order, allowing prefixes such as *ortho* or *para* as part of the name) included acetone [690–698]; benzaldehyde [699, 700]; 2-furaldehyde [701–713]; chloroformate esters [714]; 2,4-dinitrobenzaldehyde [715], *ortho*-phthalaldehyde [716], *para*-chlorobenzaldehyde, [717–719], pentafluorobenzaldehyde [720, 721]; 2,4-pentanedione [722–724]; and 3-butenone (E)-1,1,1-trifluoro-4-(3-thienyl) [725].

### 3.6.3.4 Thin-Layer and Column Liquid Chromatography

These analytical methods have been used extensively for the concentration and identification of natural products such as sugars and amino acids. There are only comparatively few applications of these methods in the analysis of hydrazines. Column chro-

**Table 45:** Derivatizing agents for GC and derivatives thus formed.

| Reagent Used               | Type of Hydrazine Analyzed | Derivative Formed                                                                                      |
|----------------------------|----------------------------|--------------------------------------------------------------------------------------------------------|
| Acetone                    | Hydrazine                  | $(\text{CH}_3)_2\text{C}=\text{N}-\text{N}=\text{C}(\text{CH}_3)_2$                                    |
| Acetone                    | MMH                        | $\text{CH}_3\text{NH}-\text{N}=\text{C}(\text{CH}_3)_2$                                                |
| Acetone                    | UDMH                       | $(\text{CH}_3)_2\text{N}-\text{N}=\text{C}(\text{CH}_3)_2$                                             |
| Benzaldehyde               | Hydrazine                  | $\phi\text{HC}=\text{N}-\text{N}=\text{C}\phi\text{H}$                                                 |
| 2,4-Dinitrobenzaldehyde    | Hydrazine                  | $(\text{NO}_2)_2\text{C}_6\text{H}_3\text{CH}=\text{N}-\text{N}=\text{CHC}_6\text{H}_3(\text{NO}_2)_2$ |
| 2,4-Dinitrobenzaldehyde    | MMH                        | $\text{CH}_3\text{NH}-\text{N}=\text{CHC}_6\text{H}_3(\text{NO}_2)_2$                                  |
| 2,4-Dinitrobenzaldehyde    | UDMH                       | $(\text{CH}_3)_2\text{N}-\text{N}=\text{CHC}_6\text{H}_3(\text{NO}_2)_2$                               |
| Furaldehyde                | Hydrazine                  |                       |
| Furaldehyde                | MMH                        |                       |
| 2-Nitrobenzaldehyde        | UDMH                       | $(\text{NO}_2)\text{C}_6\text{H}_4\text{CH}=\text{N}-\text{N}(\text{CH}_3)_2$                          |

| Pentane-2,4-dione          | MMH                        |                                                                                                        |
| Pentane-2,4-dione          | UDMH                       | $\text{H}_3\text{CCOCH}_2\text{C}(\text{CH}_3)=\text{N}-\text{N}(\text{CH}_3)_2$                       |
| Pentafluorobenzaldehyde    | UDMH                       |                                                                                                        |
| Pentafluorobenzoylchloride | UDMH                       | $(\text{C}_6\text{F}_5\text{CO})_2\text{N}-\text{N}(\text{CH}_3)_2$                                    |
| Salicylaldehyde            | UDMH                       |                     |

matography is often used as a method of sample preparation to separate the analyte from complex mixtures, such as in biological specimens. Once concentrated, other analysis methods, such as GC, in particular GC or HPLC with prior derivatization, can be used to further identify and quantify the hydrazine derivative extracted from the enriched section of the column.

As little as 0.5  $\mu\text{g}$  hydrazine can be detected by paper chromatography using *n*-butanol/6N HCl as mobile phase [726]. Picryl chloride is better than ninhydrin for developing paper chromatograms when looking for hydrazines.

A rapid and efficient procedure for determining traces of hydrazine in recovered solvents is the thin-layer chromatography (TLC) of the intensely colored azine with PDAB [727]. Hydrazine concentrations as low as 0.002% in aqueous and alcoholic media can be determined with a minimum of interference. The sensitivity of the test is enhanced by observing the TLC plate under UV light after spraying the plate with Dragendorff's spray reagent. As little as 0.2 µg will give a recognizable spot on the plate.

Hydrazine, MMH, SDMH, and UDMH as their dichloride salts can be separated by TLC on cellulose powder on glass plates, using 2-propanol/water/concentrated HCl in a volume ratio of 130:40:30 as the eluent [728]. Folin-Ciocalteu reagent was used to develop the plates and formed distinct blue spots equally well with all four hydrazines; PDAB does not react with SDMH. Using 366-nm UV light to stimulate fluorescence, hydrazine could be detected at the nanogram level after reaction with fluorescamine and isomeric phthalaldehydes [729].

### 3.6.4 High-Performance Liquid Chromatography

Essentially all methods previously described for paper or TLC can be adapted to HPLC by choosing suitable derivatives, eluents, column stationary phases, and detectors. These methods have proved particularly useful for trace contaminant/crop residue analysis. A discussion has evolved about the interpretation of the letter P in HPLC. It has been pointed out that the latest developments of the method are not using high pressure and do not deserve the attribute "high performance," since other, more efficient methods have become available. Nevertheless, we summarize the HPLC methods here that have at one time or another been used for the analysis of hydrazine and hydrazine derivatives.

#### 3.6.4.1 HPLC Analysis Without Prior Derivatization

Picogram quantities of hydrazines in the effluents of HPLC columns can be detected by chemiluminescence with ozone [730]. Because hydrazine is a reducing agent, its presence in the effluent from HPLC columns can be detected by electrochemical oxidation [731]. Regardless of which hydrazine must be analyzed, derivatized or not, miniaturized electrochemical detectors for these and similar HPLC-EC applications made the analysis more specific.

A hydrophilic interaction liquid chromatography (HILIC) method for the simultaneous determination of hydrazine, MMH, and UDMH in natural waters and soils was based on a combination of HPLC chromatographic separation on a zwitterionic sulfo-betaine stationary phase with amperometric detection and used a mixture of 78 vol. parts of acetonitrile with 22 parts of an aqueous phosphate buffer solution of pH 2.5 with an ionic strength of 20 mM as the mobile phase [732]. Detection in the direct current mode was performed at a working electrode potential of 1.1 V. The advantages of the method are the high efficiency of separation, speed, high sensitivity, and a wide

dynamic range of analyte concentrations, covering four orders of magnitude. The limits of detection were in the range 0.07–0.13 µg/L, which was two orders of magnitude lower than those achievable in previously used methods of ion chromatography with electrochemical or mass spectrometric detection.

#### 3.6.4.2 HPLC Analysis Following Prior Derivatization

Just as with GC, derivatization of hydrazine stabilizes it as a derivative for the subsequent separation and analysis by liquid chromatographic methods. The methods can also be adapted for the analysis of MMH or UDMH.

Many of the methods described here were used to determine traces of hydrazine that could be present in pharmaceutical drugs as contaminants or form in the body of patients as the hydrazine-derived drugs are metabolized. Traces of hydrazine (i.e., hydrazinium sulfate) in sulfuric acid (residual excess hydrazine after removal of NO<sub>x</sub> and free chlorine) can be determined by derivatization liquid chromatography [733].

Details of HPLC analytical methods with derivatizing agents are described in [734]. The derivatizing agents used included benzaldehyde [735–739]; salicylaldehyde [731, 740, 741]; *p*-hydroxybenzaldehyde [742]; *p*-tolualdehyde [743]; *p*-anisaldehyde [744]; naphthalene-2,3-dialdehyde [745, 746]; 2-hydroxynaphthaldehyde [747]; and 2-nitrobenzaldehyde or 5-nitro-2-furaldehyde [748, 749].

#### 3.6.5 Ion Chromatography

Ion chromatography is often performed in the same equipment as HPLC, just using ion-exchange resins instead of solid sorbents as the stationary phase. Ion chromatography can use cation-exchange resins or anion-exchange resins.

Hydrazine and hydroxylamine in aqueous solution may be determined using a Nucleosil 10SA cation-exchange column with 2mM citrate and 2mM ethylenediamine at pH 4.5 as eluent with a copper electrode [750]. Detection limits were in the range 2–10 nmol for the species examined. Alkali metal ions, ammonium ion, and hydrazinium(1+) ion can be determined simultaneously in less than 10 min. on an HPIC-CG3 column with 0.015 M HCl as the eluent [751].

A major drawback of the commonly used derivatizing agents for either GC or HPLC is that they rarely allow analysis of all three propellant hydrazines in one shot. It was therefore of interest when it was found at the NASA White Sands Test Facility (WSTF) that all three hydrazines, underivatized but in the state of their cations, could be separated by HPLC on a cation-exchange resin column using an acidic potassium phosphate buffer as the eluent [752]. DC amperometry of the eluent at a platinum electrode is specific for hydrazines since they are easily electrooxidized. Detection limits of 1 µg/L were achieved in clean wastewater samples. The only sample preparation was filtering, a substantial savings of labor over competing derivatizing/extracting methods. Similar results are possible with a gold electrode [753].

Ion chromatography with amperometric detection was applied for the direct determination of UDMH, hydrazine, MMH, and SDMH in water [754]. Selectivity of two column materials – (1) reversed phase silica modified by dodecylbenzenesulfonic acid and (2) silica with chemically bonded sulfonic acid groups – was investigated with conductivity detection. The method was used to analyze soils contaminated by spilled UDMH from crashed PROTON launch vehicles. Hydrazine and MMH were detected as decomposition products of UDMH in the soil.

An ion-exclusion chromatography method with ion-exchange enhancement of conductivity was developed for the selective separation and sensitive determination of hydrazinium ion from alkali/alkaline earth metal cations and ammonium ion [755]. Hydrazinium ions were separated by ion-exclusion/penetration effect from other cations on a weakly basic anion-exchange column in the  $\text{OH}^-$  form (TSKgel DEAE-5PW). Two different ion-exchange resin columns were inserted between the separating column and conductimetric detector in order to improve the sensitivity of hydrazinium ion. As a result, the sensitivity of hydrazinium ion using two conductivity enhancement columns could be 26 times greater than using the separating column alone. The detection limit of hydrazine ions in this system was 0.64 parts per billion (ppb).

Several methods exist for the direct determination of hydrazines in water, including ion, ion-pair, ion-exclusion, and hydrophilic interaction chromatography [756]. The separation selectivity and sensitivity of detection for each method depends on the type of sample. Direct methods are simpler than those requiring prior derivatization of samples, as was demonstrated with examples of hydrazine determination in real samples.

### 3.6.6 Capillary Electrophoresis Chromatography

Another modern analysis method suitable for the analysis of ionized compounds is capillary electrophoresis (CE). The CE method in combination with electrochemical detection (called CEEC) allows for the simultaneous determination of hydrazine, MMH, and other hydrazines in one injection without prior derivatization [757–759]. Detection of hydrazines in eluent was achieved with a palladium-modified carbon fiber microdisc array electrode. The detection limits for hydrazine or MMH were 1.2 or 2.1 pg, respectively. This is several orders of magnitude more sensitive than other chromatographic methods. Hydrazine and methylhydrazines could be separated and detected by CEEC at 1 millimol/L concentrations in a borate buffer at pH 7.18 [760].

CEEC can be used for the simultaneous detection of hydrazine and MMH using a 4-pyridyl hydroquinone self-assembled microdisc platinum electrode [761]. Such an electrode has very high catalytic capability for hydrazines, and they were detectable even at a potential of 0.0 V. The responses for hydrazine and methylhydrazine were linear over three orders of magnitude in the range 0.2–400  $\mu\text{M}$  hydrazine or MMH with

correlation coefficients of 0.9998 and 0.9991, respectively. The detection limits were  $0.1\text{ }\mu\text{M}$ .

A miniaturized analytical system for separating and detecting hydrazines was based on the coupling of micromachined CE chips with removable thick-film amperometric detectors and offered rapid (2 min) low-potential (+0.5 V vs. Ag/AgCl) simultaneous detection of hydrazine, MMH, UDMH, and phenylhydrazine at the  $1.5 \times 10^{-6}\text{ M}$  level, with linearity over the  $2 \times 10^{-5}\text{ M}$  to  $2 \times 10^{-4}\text{ M}$  range [762].

Non-aqueous capillary electrophoresis (NACE) with electrochemical detection (NACE-ED) can be used for the separation and quantitative determination of hydrazine and its methyl derivatives. The best performance of NACE-ED was achieved when using 4 mM sodium acetate/10 mM acetic acid/methanol/acetonitrile as the running buffer, with a bare platinum working electrode set at +1.0 V in an end-column amperometric detection cell [763]. The limits of detection for hydrazine, MMH, SDMH, and UDMH were 5, 2, 12, and 1 ng/mL, respectively. This is between one and two orders of magnitude lower than that achieved by previously reported CEEC methods in aqueous buffer systems in conjunction with various types of chemically modified electrodes.

Poly(methylmethacrylate) (PMMA) microchip electrophoresis separations with contactless conductivity detection, which integrates all separation and detection components in a compact portable device, enables the separation of hydrazine, MMH, and UDMH within <30 s at a separation voltage of 3.8 kV using a L(-)-histidine/2-(*N*-morpholinoethanesulfonic acid) buffer (25:50 mM, pH 5.87) [764]. The contactless conductivity detection enabled detection limits for hydrazine, MMH, and UDMH of 11.9, 35.5, and 337.8 ng/mL, respectively, with linear concentration dependence up to  $10\text{ }\mu\text{g/mL}$ . In complex matrices such as soil samples or river water, interferences were eliminated by implementing ultrasound-assisted headspace single-drop micro-extraction under strongly alkaline conditions, which led to improved limits of detection for hydrazine, MMH, and UDMH of 6.5, 15.3, and 11.4 ng/mL, respectively.

A multitude of different electrochemical detection electrode materials, many based on carbon fiber electrodes, have been developed for these CEEC hydrazine analysis applications. The same electrodes can be used for amperometric titrations (Section 3.6.10.8).

### 3.6.7 Gravimetric Methods for Analysis of Hydrazine

Gravimetric methods are a thing of the past and consume time and lack accuracy. At best, precipitation of insoluble hydrazine derivatives can be used for pre-concentrating the analyte. Benzalazine precipitates quantitatively from solutions of hydrazine and benzaldehyde [765]. Because the azine melts at 366 K, it must be dried at low temperature in a vacuum desiccator. In concentrated solutions with 50% methanol, even the intensely yellow azine formed from hydrazine with PDAB can be precipitated and weighed. It melts at 537 K and can be dried at higher temperature than the ben-

zalazine. An insoluble yellow azine precipitates from 2-nitro-1,3-indandione and hydrazine [766]. It melts at 498 K (225 °C) under decomposition.

Because the boiling points of hydrazine and ammonia are so disparate, it has been possible to do quick (but not very accurate) analyses of hydrazine/ammonia mixtures with up to 27% hydrazine by low-temperature thermogravimetry [767]. In this method, a weighed sample is slowly heated from 228 to 423 K, while the weight of the sample is recorded by an electronic balance. A typical sample weight was 40 mg. Carbon dioxide must be carefully excluded, since its potential interference by the formation of less volatile carbazic acid has not been investigated thoroughly enough.

### 3.6.8 Volumetric Analysis Methods for Hydrazine

Just like gravimetric methods, volumetric analysis methods are slowly becoming a thing of the past because they consume time and lack accuracy and require operator training. Volumetric analysis methods have traditionally been the daily chore of the analytical chemist before wet chemistry was eventually replaced by automated titrators and instrumental methods of analysis where one does not have to wash dishes afterward. As they are listed here, they only differ by the type of reaction and endpoint indication.

#### 3.6.8.1 Acidimetric Analysis Methods for Hydrazine

Acidimetric titrations are rarely used to determine any hydrazines individually, but several methods have been developed to analyze hydrazine mixtures by multi-step acidimetric titrations. Several complications are to be expected in attempts to titrate hydrazine directly acidimetrically: **(1)** A dilute alkaline solution of hydrazine will rapidly autoxidize if air is not carefully excluded prior to and during titration; **(2)** the choice of a suitable indicator is difficult since hydrazine is an even weaker base than ammonia, and salts with strong acids hydrolyze to form acidic solutions; and **(3)** hydrazine has two protonization levels. The true inflection point in less than 0.4 M solutions falls in the lower range of methyl red and in the upper range of methyl orange [768]. If the sample contains ammonia and hydrazine, it can be titrated acidimetrically first and iodometrically second to obtain numbers for both constituents.

When hydrazine is removed prior to ammonia analysis, in this case with 0.04–0.4 mM ammonia in solutions containing 0.7 mM hydrazine, there is a method where ammonia can be determined by Kjeldahl distillation and acidimetric titration following destruction of all the hydrazine with iodate in acidic solution [156, 769]. The standard deviation obtained from seven repetitive analyses was only  $\pm 0.5\%$  for ammonia in the vicinity of 8 mg of  $\text{NH}_3$  in  $\text{N}_2\text{H}_4$ . The method has also been applied to alkyl- and arylhydrazines without additional ammonia generation during the removal of the hydrazines.

Mixtures of 5–10% hydrazine in ammonia, such as those expected to be formed by nucleofission synthesis of hydrazine from ammonia, can be analyzed by first reacting the hydrazine only in acidic solution with bromine (liberated in solution by mixing potassium bromate and potassium bromide solution) [770]. Excess bromine is then converted to free iodine by the addition of potassium iodide, and the iodine is backtitrated with sodium thiosulfate to a starch (or potentiometric) endpoint. One mol of hydrazine is equivalent to four equivalents of bromate. Next, a second sample is also mixed with bromate and bromide, acidified to liberate bromine (this is done in a bromination flask or an iodine number flask with tightly sealing ground glass stopper), and then rendered alkaline to form hypobromite by adding 6N NaOH until the color of the solution changes from brown to pale yellow. The reaction of hypobromite with ammonia

varies slightly with alkalinity. When samples contain both ammonia and hydrazine, hydrazine is analyzed first in acidic solution and then subtracted from the total equivalents of bromate consumed in the second reaction in alkaline medium. The relative standard deviation in either ammonia or hydrazine results was on the order of 0.22–0.36%.

### 3.6.8.2 Acidimetric Titration Following Reaction with Organic Compounds

The pKs of hydrazine and UDMH or MMH are too close to allow simultaneous titration of two or three bases in aqueous solution. Following derivatization of hydrazine and UDMH, however, the acidity of the resulting azines when titrated in non-aqueous media (acetic acid) with perchloric acid in dioxane is distinctly different. Derivatization allows separate titration of different hydrazines and may also help in achieving sharper endpoints. Carbonyl compounds used to derivatize hydrazines in this application include salicylaldehyde [771–773] and acetone [774].

Instead of forming derivatives with salicylaldehyde, the different rate of acetylation of hydrazine and UDMH or hydrazine and MMH with acetic anhydride provides the basis for a method to analyze binary hydrazine mixtures [775–778]. In acetonitrile, both hydrazine and MMH react almost immediately, whereas the acetylation of UDMH proceeds very slowly. Total basicity of an unacetylated sample is determined by titration with standardized perchloric acid in acetic acid with quinaldine red indicator.

Hydrazine and its methylated derivatives can be differentiated not only by reaction with acetylating agents or azine-forming reagents but also by acidimetric titration before and after reaction of the sample with isocyanates [779].

Traces of water in hydrazine are strongly ionized

and form the acid hydrazinium ion. Small amounts of water in hydrazine can be determined by titrating this “acid” with a strong base, such as standardized 0.1 molar

sodium hydrazide in hydrazine [780]. This reaction must be carried out under the exclusion of air. Endpoint indication is possible with a potentiometer, a platinum electrode, and a Cd/CdSO<sub>4</sub>/0.2M H<sub>2</sub>SO<sub>4</sub> reference electrode. Special precautions are required when preparing the sodium hydrazide solutions to avoid explosions.

Hydrazinium salts of weak or medium-strength acids may have acidic or basic properties, depending on the solvent used. They can be titrated in non-aqueous media with potentiometric endpoint indication. Thus hydrazinium(1+) nitrate can be titrated as an acid in pyridine solvent using tetrabutylammonium hydroxide as the titrant. A glass/thallium amalgam electrode pair was used to sense the equivalence potential. If hydrazinium(1+) nitrate is to be determined as an acid, dimethyl sulfoxide or glacial acetic acid can be used as the solvent. In the case of glacial acetic acid, the preferred titrant is 0.05 N perchloric acid in acetic acid [781–783].

A combination of derivatization with salicylaldehyde and acidimetric titration with potentiometric endpoint indication in non-aqueous solvents used perchloric acid in acetonitrile, nitrobenzene, or acetic acid [784]. The Schiff base formed with hydrazine was the least basic azine of the ArCH=N(CH<sub>2</sub>)<sub>n</sub>N=CHAr series (*n* = 0 to 4) tested. An increase in the number of central —CH<sub>2</sub>— groups increased the basicity of the Schiff bases.

Mixtures of hydrazine, MMH, or UDMH with diethylene triamine can be analyzed in a non-aqueous titration system using methanol as a solvent, hydrochloric acid in methanol as the titrant, and bromocresol green as indicator [785]. The method uses the reactions of salicylaldehyde, which forms neutral azine with hydrazine, neutral hydrazones with MMH and 1,1-dimethylhydrazine, and a basic Schiff base with diethylene triamine. The total basicity of the admixtures is determined on separate aliquots of the mixtures before and after the addition of salicylaldehyde.

Mixtures of hydrazine, hydrazinium nitrate, ammonia, and water can be analyzed by titrating the mixture with standard acid before and after reacting it with acetone or, in a separate test, with formaldehyde [786, 787]. The procedure employs successive acidimetric titrations on a single sample as follows:

- Neutralization of the sample with standard acid to determine the total basic components (hydrazine and ammonia).
- Reaction of the hydrazinium ion with excess acetone forming dimethylketazine, and titration of the acid liberated with standard base. This determines the sum of free and combined hydrazine (hydrazine and hydrazine salt):

- Reaction of ammonium ion with excess formaldehyde forming hexamethylenetetramine and titration of the acid liberated with standard base. This determines ammonia:

- d. Subtracting the result for ammonia from the result for total basic components determines hydrazine. Subtracting the result for hydrazine from the result for free and combined hydrazine determines hydrazine salts. The remainder of the sample was assumed to be water. The results were then compared with titrating the total hydrazine with potassium iodate in hydrochloric acid solution.

### 3.6.8.3 Redox Titration Analysis Methods for Hydrazine

Because of the multitude of oxidizers that have been more or less successfully tried as oxidants for the redox titrations of hydrazine, a systematic approach must be followed in discussing these analysis methods. The following discussion covers redox titrations in the sequence of groups in the periodic table of elements, arranged by the active atom that changes its state of oxidation. The review starts with group VIII and proceeds from right to left toward group I. In this arrangement, the halogens and halogenates are discussed first, and copper(II) sulfate (group Ib) is discussed last.

In evaluating several different methods for the analysis of hydrazine and its methyl derivatives, both iodate and bromate titrations were conducted for hydrazine, MMH, UDMH, and SDMH [788]. In the iodate titration using chloroform extraction of purple iodine as a visual indicator, hydrazine reacted on a 1:1 molar basis, but UDMH reacted on an iodate:UDMH = 1:2 ratio. As an alternative, the four hydrazines can be titrated potentiometrically with 0.016 M  $\text{KBrO}_3$  when the samples are dissolved in 20 mL concentrated HCl containing 2 g KBr.

### Redox Titrations with Visual and Other Non-Electric Endpoint Indication

Analysis methods for hydrazine by redox titrations have been evaluated as early as 1924. Iodic acid, iodine, bromine, and hypochlorite were tried as oxidants, but iodic acid or potassium iodate in acidic solution was quickly recognized as the most desirable oxidizer [789]. Only the methods of endpoint indication were initially very cumbersome, and usually the excess oxidant had to be backtitrated iodometrically. The methods listed in this first section operate without electronic endpoint indication, but they would work just as well or even better with electronic endpoint indication. Methods that depend on electronic instrumentation for endpoint indication are summarized in a following section. For a more detailed summary of analytical methods for hydrazine(s) using a variety of oxidants, see [790]. That thorough resource contains sections on the following oxidizers: potassium hexacyanoferrate(III), bromine monochloride, bromine, potassium chlorate, sodium hypobromite, potassium bromate, iodine, potassium iodate, potassium permanganate, potassium peroxodisulfate, selenous acid, potassium dichromate, chloramine-T, *N*-bromosuccinimide, potassium or ammonium vanadate, cerium(IV) nitrate or cerium(IV) sulfate, and methods for visual endpoint indication. The endpoints of redox titrations can also be recognized by thermometric titrimetry [791, 792].

Hydrazine has been determined by its oxidation to nitrogen with a known excess of bromine. Bromine in acidic medium bleaches the dye methyl red. A known excess of bromine when treated with hydrazine is reduced to bromide, and the unreacted bromine is determined spectrophotometrically using methyl red [793–795]. The molar absorptivity of methyl red was calculated to be  $9.95 \times 10^4 \text{ L mol}^{-1} \text{ cm}^{-1}$ . The method obeys Beer's law in the range 0–6  $\mu\text{g}$  of hydrazine in an overall aqueous volume of 25 mL with a correlation coefficient of 0.999. The detection limit was 0.25  $\mu\text{g}$ . The method has been successfully applied for the determination of hydrazine in boiler feedwater samples. The results obtained with the bromine-methyl red method compared well with the PDAB method.

### Redox Titrations with Potentiometric or Amperometric Endpoint Indication

Potentiometric or amperometric endpoint indication is more accurate than visual endpoint indication and can be applied to titrations with most of the oxidizers listed in the preceding section. Redox titrations with potentiometric or amperometric endpoint indication are summarized in [796], where additional information on redox titrations can be found.

Oxidizers used for redox titrations with potentiometric or amperometric endpoint indication include iodine, iodine(I) chloride, potassium iodate, potassium periodate, potassium bromate, potassium permanganate, molybdates, chromates, chloramine-T, chloramine-B, cerium(IV) nitrate, cerium(IV) perchlorate, and cyanogen bromide.

Depending on the pH and the amount of additional hydrochloric acid present during titration, the reduction of iodine(V) by hydrazine sulfate can proceed to different states of oxidation, and the three different equivalence points (resulting in iodine monochloride, free iodine, or iodide ion) can be visualized by plotting the electrochemical potential against a reference electrode [797]. Sometimes a layer of chloroform is used to extract the free iodine and make it visible by its purple color for visual endpoint indication.

The endpoint during the titration of hydrazine with iodine or iodate can also be recognized using an iodide-selective electrode [798, 799]. As little as 13 ng hydrazinium(2+) chloride has been determined by this method in the absence of other reducing agents. The reproducibility was like that of the direct potentiometric methods (2–3% in  $10^{-5} \text{ N}$  solutions).

### 3.6.9 Gasometric and Manometric Analysis Methods

Many hydrazine compounds give quantitative yields of dinitrogen gas on treatment with iodate in a Warburg apparatus. The ready availability of high-purity hydrazinium(2+) sulfate caused several investigators to choose this salt as a standard for the calibration of their gasometric apparatus. The reaction proceeds rapidly with hydrazine, MMH, and numerous monoacyl hydrazides of industrial and pharmacological interest [800]. With hydrazine in the form of hydrazinium(2+) sulfate, the

mean nitrogen recovery of four subsequent analyses was 99.5% with a standard error of  $\pm 1.2\%$ . See also [801]. Other hydrazine derivatives can be analyzed by gasometric microdetermination by oxidation in basic media [802, 803].

### 3.6.10 Electroanalytical Methods for Hydrazine

Electrochemical analysis methods are becoming increasingly popular because they can be automated and made to interface with digital data acquisition and data reduction. Electrochemical analysis methods include coulometric, potentiometric, and amperometric methods.

#### 3.6.10.1 Coulometric Analysis Methods for Hydrazine

Because of the different routes of hydrazine oxidation in acidic, neutral, or alkaline solutions, coulometry is a suitable method for the direct oxidation of hydrazine, provided that all conditions are kept constant. The mechanism of the electrooxidation of hydrazine was already discussed in Section 3.2.

Hydrazine in the presence of ammonia in aqueous acidic solutions could be determined with a relative standard deviation of 0.09% by direct coulometry in 1 M sulfuric acid with a platinum analytical electrode, a platinum wire helix auxiliary electrode, and a mercury/mercury(I) sulfate reference electrode [804, 805]. The oxidation was carried out at a potential of +0.410 V versus the mercury/mercury(I) sulfate reference electrode. This method was used to determine less than 10% hydrazine formed in anhydrous ammonia in a chemonuclear reactor. The amount of hydrazine in the analysis cell ranged from 55 to 440  $\mu\text{g}$ . Measured coulombs consumed for the oxidation were linear with concentration within this range.

Electrogenerated iodine or bromine performed equally well in the coulometric titration of hydrazine [806]. Electrogenerated iodine in methanol as a solvent and in the presence of potassium acetate as a buffer allows the coulometric determination of hydrazine [807]. Iodine in the plus one state of oxidation  $\text{I}^{+1}$  can be electrogenerated from iodobenzene or 4-iodonitrobenzene in 0.2-M  $\text{HClO}_4/\text{AcOH}$  solutions on a Pt electrode and used for coulometric titration of hydrazine and hydrazine compounds [808].

A rapid and automatic coulometric titration procedure for the determination of hydrazine and monosubstituted hydrazines in the 3- to 5-mg range with electrolytically generated bromine had a standard deviation of approximately  $\pm 1\%$  [809]. The use of anodically generated chlorine in place of bromine did not result in any improvements. An acetic acid/water/methanol/mercury(II)acetate/potassium bromide solvent was used for most of the compounds titrated. Other solvents tested were aqueous 0.3 M hydrochloric acid with 0.1 M potassium bromide and 80% acetic acid/20% water 1.0 M in hydrochloric acid with potassium bromide. The choice of solvent depends on the type of hydrazine to be titrated. Hydrazine, MMH, phenylhydrazine, and acetylhydrazine consumed close to four equivalents of bromine, and the reaction was rapid. UDMH consumed close to six (5.88) equivalents, and the results were repro-

ducible. A similar method in a microcell holding a tiny 0.5 mL sample volume has extended the sensitivity range to micromol quantities of hydrazine [810].

All three propellant hydrazines (hydrazine, MMH, UDMH) from sulfuric acid-impregnated air sampling tubes or wastewater samples can be analyzed and titrated coulometrically with electrically generated chlorine or bromine, but the method does not differentiate between the three hydrazines [811]. This method is faster than many competing methods since it does not require derivatization or internal standards for calibration. At the lower limit of sensitivity, nanomols of hydrazines can be detected, which translates to ppb concentrations in air samples. Coulometric titration does not differentiate between hydrazines and hydrazones, which are contaminants in samples. In samples that contain MMH and UDMH autoxidation and partial oxidation products, various amounts of formaldehyde hydrazones will be found that may also consume some of the oxidizer. Formaldehyde (a UDMH oxidation product) and its hydrazones are also oxidized by either free chlorine or bromine, but the stoichiometry is different from that with pure hydrazines. In samples with large amounts of methylhydrazines and their autoxidation products, the coulometric titration results can be corrected by determining formaldehyde (from the hydrolysis of the methylhydrazones) colorimetrically with chromotropic acid in concentrated sulfuric acid.

Electrogenerated bromine allows the side-by-side determination of ammonia and hydrazine in boiler feedwater with biamperometric or bipotentiometric endpoint indication [812]. The electrolysis cell is separated by a glass diaphragm. At first the hydrazine is titrated at pH 0.5 to 7 in 0.3 N  $\text{H}_2\text{SO}_4$ , then a borax buffer is added, and ammonia is titrated at pH 8.2 to 8.5.

Direct coulometric titration of hydrazine, MMH, or acetylhydrazine with electrically generated bromine in acetic acid gave good results [813]. 0.9 M  $\text{CH}_3\text{COONa}$  or  $\text{CH}_3\text{COOK}$  in glacial acetic acid provided a good anode electrolyte. Contamination by no more than 4% water could be tolerated, but none by acetanhydride. Similar conditions, also in acetic acid, were used to titrate hydrazine with electrically generated  $\text{Pb}(\text{CH}_3\text{COO})_4$  [814].

A coulometric flow titration with electrogenerated bromine was combined with chemiluminescent and amperometric flow detection to determine small concentrations of hydrazine and ammonium. Hydrazine could be titrated in a range between 2  $\mu\text{M}$  and 1.1 mM with chemiluminescence detection of the equivalence points [815]. The lowest concentration of hydrazine that could be titrated was 60 nM. Ammonia concentrations lower than 0.5 mM did not influence the titration results. Between pH 1 and 7 hydrazine can be selectively titrated in the presence of ammonium. The sum of hydrazine and ammonia/ammonium can be titrated at pH 8.3 with amperometric detection. Hydrazine and ammonia were titrated precisely in their mixtures and in concentration ranges between 20  $\mu\text{M}$  and 0.5 mM.

### 3.6.10.2 Polarographic Analysis Methods for Hydrazine

Polarography is a subclass of voltammetry where the working electrode is a dropping mercury electrode. Voltammetry is the study of current as a function of applied potential. The potential is varied arbitrarily either step by step or continuously, and the current value is measured as the dependent variable.

The polarographic behavior of hydrazine has been studied by many researchers, and there is general agreement that polarography is not a suitable method for the quantitative estimation of hydrazine itself in solution. Nevertheless, polarography can be applied after the hydrazine is converted to organic derivatives, such as benzalazine. This conversion is quantitative, and the azine can be analyzed by polarography just like many other reducible or oxidizable compounds. Another topic discussed in this section is polarography in hydrazine or hydrazine hydrate as a solvent.

It was shown that neither the half-wave potential nor the ratio of limiting current to hydrazine concentration was independent of the hydrazine concentration, which makes it impossible to obtain exact analytical results [816]. Dinitrogen was identified as the main product of anodic oxidation of hydrazine in alkaline solutions [817]. None of the methods was useful for the quantitative analysis of hydrazine.

An attempt was made to explain the mechanism of the electrooxidation of hydrazine that is responsible for the irregularities in polarography [818]. Dinitrogen is the main product of electrooxidation of hydrazine at a mercury-coated platinum electrode. Under some conditions, ammonia is also formed as a result of diimide dimerization.

The complex mechanism of the anodic oxidation of hydrazine has been extensively studied with respect to the use of hydrazine in fuel cells. Whereas sharp half-wave potentials cannot be achieved for hydrazine in aqueous solution, both hydrazine and hydrazine hydrate gave well-defined one-step anodic chronopotentiograms in dimethyl sulfoxide (DMSO) as a solvent [819]. The oxidation of hydrazine in aprotic solvents proceeds as a one-electron process:

When mercury electrodes are used in hydrazine polarographic studies, it must be kept in mind that hydrazinium ions, like many alkali metals and organic “onium” ions, can form an amalgam with mercury. The amalgam formation may change the electrode potentials.

Even though the results may not have been reproducible enough to be useful for quantitative analysis, the half-wave potentials of hydrazine on a rotating platinum disc electrode were measured in neutral and acidic solutions [820]. The hydrazine concentrations were  $8 \times 10^{-5}$  to  $1.3 \times 10^{-3}$  M. Two oxidation half-waves were observed: The first occurred at a potential of  $-0.2$  to  $+0.4$  V, depending on the supporting electrolyte ( $0.5$ – $8$  M  $\text{H}_2\text{SO}_4$ ,  $1$  M  $\text{HNO}_3$ ,  $\text{AcOH-AcO}^-$  buffer at pH 4.6). The second occurred at or above  $+0.7$  V, but only if the hydrazine concentration was in excess of  $6 \times 10^{-4}$  M. The magnitude of the current depended on the surface state of the platinum, which

changed because of adsorption of  $N_2H_4$  or its oxidation products. All data indicated that the oxidation reaction is diffusion controlled.

Polarization curves of the electrooxidation of hydrazine on mercury, silver, and gold electrodes in alkaline solutions on a mercury drop electrode were obtained varying concentration, ionic strength, and pH of the solution and on rotating silver and gold disc electrodes varying concentration and pH of the solution, and speed of rotation of the electrode [821]. Polarization curves on the silver electrode seemed to be independent of pH. The half-wave potential of the oxidation of hydrazine on the mercury electrode was independent of the potential difference across the diffuse double layer. The process at the silver electrode was direct discharge of the hydrazine molecule. The rate-controlling process in the oxidation at the mercury and gold electrodes was either a two-electron electrode reaction with the participation of hydroxide ions or a chemical volume or surface reaction of the product of a one-electron reversible oxidation.

One method for the voltammetric determination of hydrazine and hydroxylamine involves conducting a sweep to measure the current plateau at pH 5.0 with a rotating Pt electrode before and after the addition of acetone [822]. This method was used to determine the two hydronitrogens in concentrations from 0.32 to 5.7 mg/L with standard deviations of 2 to 5%.

Hydrazines can be determined by voltammetry, based on their hydrogen catalytic wave in formaldehyde-platinum-sulfuric acid media [823]. Adsorption of the platinum-formazone complex on the hanging mercury drop electrode enhanced the sensitivity, allowing convenient measurement of micromolar and submillimolar concentrations of simple hydrazines. The selectivity was better than that of conventional (anodic) measurements of hydrazine(s) because oxidizable compounds did not interfere. The sensitivity was also greatly improved at concentrations down to  $10^{-6}$  M. The hydrazine response was evaluated with respect to pre-concentration time, concentration dependence, platinum and formaldehyde concentrations, reproducibility, and other variables. The relative standard deviation (at  $2 \times 10^{-5}$  M) was 1.6%.

Another polarographic method used 5-nitrosalicylaldehyde to derivatize hydrazine prior to polarographic determination [824]. The method is suitable for hydrazine concentrations in a range of 0.25–5 mg/L. The aldazine that is formed by the reaction

is insoluble in water. It is filtered and re-dissolved in 0.1 N NaOH. Polarography is then carried out in this solution and is free from interference. Neither MMH nor UDMH interferes.

A nanoporous gold electrode demonstrated a high sensitivity to hydrazine oxidation. Hydrazine was detected by hydrodynamic chronoamperometry at +0.2 V (vs. Ag/AgCl) [825]. The steady-state oxidative current exhibited a linear dependence on the hydrazine concentration in a concentration range of 5.00 nM–2.05 mM, and the detection limit was 4.37 nM. This detection limit is lower than the detection limits reported in the literature.

### 3.6.10.3 Anhydrous Hydrazine as Solvent for Polarographic Studies

In addition to polarographic studies where hydrazine becomes oxidized, there are also numerous studies where hydrazine or its aqueous solutions merely serve as a solvent. These measurements of current-potential curves discussed here relate closely to the study of the corrosion mechanism of metals in hydrazine and solutions of hydrazinium salts in hydrazine.

Polarographic curves of numerous metals as electrodes have been measured in anhydrous hydrazine solutions with hydrazine as solvent. The objective of these studies was to find materials that are compatible as storage tank containers or resist corrosion when used as fuel cell electrodes or electrodes in hydrazine electrolysis units. For the latter application, electrodes with low overpotential were also sought. A cadmium reference electrode prepared by the deposition of cadmium from cadmium sulfate in 2M H<sub>2</sub>SO<sub>4</sub> or hydrazine was used to study anhydrous hydrazine as a solvent [826]. This electrode had a potential of –0.246 V against the normal hydrogen electrode in hydrazine.

The reduction of Fe<sup>2+</sup>, Co<sup>2+</sup>, Ni<sup>2+</sup>, and Cu<sup>2+</sup> ions in anhydrous hydrazine and in hydrazine-water mixtures was measured, but attempts to measure the potentials of alkaline and alkaline earth metal ions in anhydrous hydrazine were not successful because the potential was below –0.7 V [827]. The most sudden potential jump was observed in the reduction of Ni<sup>2+</sup>. The polarization currents resulted in a linear function when plotted against nickel concentration.

A potentiostatic setup with three electrodes was used to study the electrochemical behavior of nickel electrodes in anhydrous hydrazine [828]. A solution that was 1 molar in hydrazinium chloride was highly corrosive, and the solution turned pink. A similar reaction was observed with hydrazinium azide. In neutral medium or when potassium chloride instead of hydrazinium chloride was added, the nickel was not corroded by hydrazine. The authors have also recognized the contribution of carbazic acid to the corrosion of nickel in hydrazine. Carbazic acid is formed by the absorption of atmospheric carbon dioxide into the hydrazine if the solution is not protected from air during the experiment.

Currently, both chloride and carbon dioxide are analyzed in MIL-SPEC high-purity grade hydrazine to show compliance with this propellant specification. The main con-

cern is that these contaminants contribute to the corrosion of tanks and valves in flight systems. However, both carbon dioxide and chloride are poor indicators of hydrazine corrosivity. Both may exist in hydrazine as inactive species or active species. The actual active species in both cases is thought to be the hydrazinium ion, which may also be formed by the addition of water to anhydrous hydrazine. So far, there is no specific and reliable method for the analysis of  $\text{N}_2\text{H}_5^+$  in hydrazine. An attempt was made to analyze  $\text{N}_2\text{H}_5^+$  in hydrazine by polarographic techniques [829]. Such methods have the advantage that they can work with small (2-mL) samples and give an almost immediate readout that indicates the level of contamination in the hydrazine. A mercury drop electrode was used, and a range of 0.0 to  $-0.5\text{ V}$  was swept each time. Pure hydrazine was spiked with known levels of contaminant in an attempt to identify the various peaks observed. No assignments were made to the anions, such as carbazate, carbamate, carbonate, chloride, or sulfate. The polarogram wave ("peak") heights at  $-0.64$  and  $-0.74\text{ V}$  were proportional to the amount of dry  $\text{CO}_2$  gas added in the range below 30 ppm by weight in hydrazine. This appears to be a useful range for analysis. When copper(II) sulfate was added to anhydrous hydrazine that also contained some previously added HCl, a well-defined wave was observed for  $\text{Cu}^{2+}$  at  $-0.16\text{ V}$ . See also [248, 830].

#### 3.6.10.4 Potentiometric Analysis Methods

Potentiometric analysis methods passively measure the potential of a solution between two electrodes, causing no changes to the solution in the process, so that it is a non-destructive measurement. One electrode serves as the reference electrode and has a constant potential, while the other one is an indicator electrode whose potential changes with the composition of the sample. The difference in potential between the two electrodes gives a signal proportional to the concentration of the analyte in the solution. Potentiometry usually uses indicator electrodes made to be specifically sensitive to the ion of interest, such as fluoride in fluoride-selective electrodes, so that the potential depends solely on the activity of this ion of interest.

There are electrochemical sensors for hydrazine vapors in air that are an important part of leak detection and workplace air surveillance and monitoring. The instruments can continuously record the hydrazine concentration in air and trigger an alarm if a certain threshold concentration is exceeded. The electrodes in these instruments are embedded in a non-volatile, gelled electrolyte and separated from the air by a semi-permeable membrane. These instruments will be described in Section 3.6.15.12.

#### 3.6.10.5 Redox Potential Measurements in Aqueous Solutions

In the absence of other oxidants or reductants, the redox potential of a properly activated electrode in relation to a standard electrode may serve as an indicator of the amount of hydrazine present. The main application of hydrazine redox potential measuring electrodes is for metering hydrazine hydrate for the deoxygenation of boiler

feedwater. Similar instruments could be used to measure hydrazine in wastewater, but they would work only in the absence of other reducing contaminants.

Commercially available boiler feedwater analyzers with platinum/stainless-steel electrodes have been adapted to analyze hydrazine vapor concentrations in air [831].

#### 3.6.10.6 Ion-Selective Electrodes for Analysis of Hydrazine

Ion-selective electrodes have become increasingly popular during the past decade because they offer the possibility for fast analysis of ions in solutions. Although many ions interfere and the electrodes are not always as selective as one would wish, these electrodes have already been used in the analysis of hydrazine. The excess of chloramine-T remaining after complete reaction of hydrazine can be determined with a chloramine-T ion-selective electrode [832]. With this method 0.06 to 3 mg of hydrazine could be determined with a relative standard deviation of 2%.

Hydrazine in the absence of other reducing media can be determined indirectly after reaction with excess iodate using an iodide-selective electrode [799]. Hydrazinium(2+) dichloride can be determined at concentrations of 13 ng  $\text{N}_2\text{H}_6\text{Cl}_2/\text{mL}$  with this method.

A similar method established a detection limit of  $5 \times 10^{-5}$  mol/L by reacting hydrazine hydrate solutions with iodine in an alkaline medium, then determining the iodide at pH 2 to 5 [833]. Excess free iodine was extracted with chloroform prior to the iodide measurement. The calibration curve was linear from  $5 \times 10^{-5}$  to  $5 \times 10^{-3}$  mol/L.

Chloride in H-70 fuel mix can be analyzed with ion-selective electrodes after dissolving the NVR in 1-N  $\text{H}_2\text{SO}_4$  and neutralizing with 1-N NaOH [675]. Calibration standards must be prepared in solutions of identical ion strength.

The fluorine atom in 1-fluoro-2,4-dinitrobenzene is sufficiently activated that it reacts directly with hydrazine, releasing fluoride ions. The fluoride ion can subsequently be determined with an ion-selective electrode, and its concentration is directly proportional to the original amount of hydrazine in the sample [834]. Calibration was linear over a range from  $10^{-4}$  to  $10^{-2}$  M.

#### 3.6.10.7 Chronopotentiometric Analysis Methods for Hydrazine

A variant of potentiometry is chronopotentiometry, which consists in using a constant current and measurement of potential as a function of time. Study of the depolarization kinetics of an anodically polarized electrode was the basis for a quantitative method for analysis of hydrazine by chronopotentiometry [835]. When plotting the logarithm of the potential versus the logarithm of time, straight lines are obtained for constant hydrazine (= hydrazinium sulfate in 1-N  $\text{H}_2\text{SO}_4$ ) concentration. The location of these well-defined parallel lines is determined by the amount of hydrazine present. The slope of the lines is dependent on the electrolyte and is not affected by the concentration of added reductants. Platinum is a suitable electrode material for chronopotentiometric oxidation of hydrazine [836]. In a study of the effect of electrode pre-treatment on the anodic oxidation of hydrazine in sulfuric acid solutions,

reaction occurred with the smallest activation overpotential at a platinized electrode over a concentration range of 0.5 to 25 mM hydrazine. Several possible mechanisms for this variation, involving adsorption of hydrazine, bubble formation, occurrence of an intermediate chemical reaction, and catalytic decomposition of hydrazine at the electrode surface, were considered.

#### **3.6.10.8 Electrodes for Electrochemical Analysis of Hydrazine in Water Flow Injection Analysis with Electrochemical Detectors**

Hydrazine solutions can be analyzed continuously by a flow injection analysis method with an amperometric detector (Pt electrode, Ag tube) [837]. The hydrazine calibration curve covered the concentration range  $10^{-4}$  to  $10^{-3}$  mol/L with 20  $\mu$ L samples.

Continuous, online flow injection analysis of hydrazine or semi-carbazide is possible by first reacting with a freshly HCl acidified, previously neutral iodate/iodide solution, and then analyzing the eluent amperometrically at a platinum electrode [838]. In this method, iodine is produced online in a flow injection system by the injection of hydrochloric acid or sulfuric acid into neutral or slightly alkaline iodide/iodate eluent and is determined amperometrically at a platinum electrode. Compounds like hydrazine that can be oxidized or iodinated by iodine are determined by injecting them, in acid solution, into the iodide/iodate eluent and the excess of iodine after reaction with organic compound is determined by flow injection analysis amperometry at a platinum electrode.

A bromine stream can be used to titrate a hydrazine stream and any excess bromine determined as previously [839]. Ammonia and hydrazine in the range  $0.05 \times 10^{-3}$  to  $0.7 \times 10^{-3}$  M were determined with a relative error of <5% by reaction with  $1 \times 10^{-3}$  M hypobromite in phosphate buffer solution (pH 9.8) and determining the excess of hypobromite by flow injection voltammetry. Hydrazine is then calculated as the difference between the two voltammetric readings.

#### **Electrodes for Other Electroanalytical Applications**

In addition to flow injection analysis, flow-through amperometric detectors have found widespread use for the measurement of electroactive, reducible, or oxidizable species in the effluent of liquid chromatographs (Section 3.6.4), ion chromatographs (Section 3.6.5), or capillary electrophoresis chromatographs (Section 3.6.6). Hydrazine and most of its organic derivatives are oxidizable and readily detected by electrooxidation. Besides being specific to hydrazines, electrochemical detectors in this application offer excellent sensitivity, wide linear range, and low dead volume. A problem with many analytes is that they undergo electrooxidation only at electrode potentials substantially different from their redox potentials predicted from thermodynamic calculations. One method to minimize overpotential is the use of chemically modified electrodes with catalytic properties. A wide variety of electrode materials has been tested for this application. Initially those were mostly platinum

group metal electrodes, but later many other conductive and catalytically active materials were used as electrodes. Several of these electrode materials were already summarized in [840]. That information need not be repeated here. A few more recent additional examples are listed here for updates and improvements on those electrode materials and analysis methods. Many of these electrode materials are also of interest for electrodes in fuel cells.

Much effort has been devoted to facilitating the amperometric detection of hydrazines, including using pre-anodized glassy carbon electrodes and various chemically modified electrodes. Electrode materials for the electrocatalytic oxidation of hydrazine included single crystal surfaces of platinum [841, 842]; various polycrystalline metal electrodes (Ni, Co, Fe, Cu, Ag, Au, and Pt) [843];  $\text{Ni}_{0.87}\text{Zn}_{0.13}$ ,  $\text{Ni}_{0.95}\text{La}_{0.05}$ , and  $\text{Ni}_{0.85}\text{La}_{0.15}$  [844–846]; glassy carbon or vitreous carbon [847–871]; carbon fiber and carbon nanotube electrodes [872–888]; metal-phthalocyanine-coated electrodes [889–903]; or hexacyanometallate (Prussian Blue) coated electrodes [847, 849, 904, 905]. Electrodes with nanosize metal particles [906–910] or metal oxide electrodes [911, 912] have been examined. See also [853, 913–915].

### 3.6.11 Spectrophotometric Analysis Methods for Hydrazine

Of all analytical methods, spectrophotometric methods offer the most versatile applications, and they are easily adapted to different reagents [916]. Most of these methods operate in absorption, but a few also operate by analyzing light emitted by fluorescence from the sample undergoing analysis.

#### 3.6.11.1 UV-Visible Spectrophotometric Analysis Methods for Hydrazine

Direct UV spectrophotometric methods without the addition of color-forming reagents can be used for hydrazine itself (in the absence of any colored organic contaminants) or for the analysis of contaminants like aniline in standard-grade hydrazine. For direct UV spectrophotometric analysis of hydrazine hydrate in water (in the absence of other contaminants) some investigators have attempted to use the absorption at 280 nm without being aware that until the year 2000, H-70 propellant-grade hydrazine typically contained some aniline since it was usually made by diluting anhydrous standard propellant-grade hydrazine with water [917]. It must be assumed that the absorption at 280 nm shown was actually that of aniline and not of hydrazine (cf. spectra reported in Section 2.4.1).

Aniline in hydrazine can be determined by UV spectrophotometry. The aniline absorption peaks at 280 nm and appears as a shoulder of a broader hydrazine peak located at shorter wavelengths [918]. The exact location of the shoulder depends on the hydrazine dilution. One must extrapolate to an imaginary baseline or use Fourier transform peak analysis to obtain the contribution of aniline at that wavelength, which makes this a difficult analysis to perform. This analysis method was described in several editions of the military specification MIL-P-26536, summarized in Table 42.

Attempts have been made to extract the aniline from hydrazine with cyclohexane (by multiple extraction) and measure the aniline UV absorption in the hexane extract.

**Visible Light Spectrophotometric Analysis Methods for Hydrazine.** Many of the spectrophotometric methods operating in the visible range have the advantage that they are easy to perform, are specific to hydrazines, and do not require very costly equipment. Therefore, for the analysis of trace quantities of hydrazine in air or water, spectrophotometric methods are frequently used either for routine analysis or to calibrate electronic direct-reading instruments that are based on non-spectroscopic principles. They typically involve the reaction of a sample in water with a color-forming reagent that is more or less specific to hydrazine. These methods are not suitable for performing assays on pure hydrazines because of the large dilution required to bring the absorbance into the range of the instrument and the need to stay within the linear range of the calibration.

Because of the large number of color-forming reagents available, the material in the following section had to be arranged somehow in a systematic order. The methods and reagents are listed here in alphabetical order by reagent name. The prefix *p*- or *o*- is recognized as the letter of the alphabet by which the reagents are sorted in alphabetical order. Similar color-forming reagents are available for the analysis of MMH or UDMH (chapters “Methylhydrazine” and “Dimethylhydrazines”). This arbitrary alphabetical arrangement does not necessarily reflect the order of importance of the respective method. If ranked by importance and frequency of use, the PDAB methods should probably be listed first.

A review of the main approaches to determining hydrazine and its derivatives by spectrophotometric and fluorometric methods included 122 references to the literature [919]. Reagents for the spectrophotometric analysis of hydrazine(s) include benzofuroxazan reagents [920–922]; bindone [671, 923]; 1-chloro-2,4-dinitrobenzene [924]; chromium [925, 926]; glutaconaldehyde [663, 927–929]; colloidal gold, nanogold [930]; 2-hydroxy-1-naphthaldehyde [931–933]; molybdenum blue [934]; molybdatophosphoric acid, phosphomolybdic acid [935–938]; 5-nitro-2-furaldehyde [939]; PDAB [940–972]; picryl chloride [973]; potassium permanganate [974]; thiophene-3-carboxaldehyde (3-thienaldehyde) [975]; vanillin (4-hydroxy-3-methoxy-benzaldehyde) [972, 976, 977]; and veratraldehyde [978].

Indirect spectrophotometric methods proposed for the analysis of hydrazine, MMH, and several hydrazides would not be specific to hydrazine but would respond to all reducing agents. It also would not work if the hydrazine already contained some iron. This method is based on the reaction of a nitrogenous reducing substance with ferric iron at 358 K (85 °C) in acetate buffer solution containing 2,2'-bipyridyl and on the determination of the resulting ferrous-bipyridyl complex spectrophotometrically [979].

### 3.6.11.2 Infrared Absorption Spectrophotometric Methods

The IR absorption of water in hydrazine, MMH, or UDMH obeys Beer's law [980]. Using the 1.9- $\mu\text{m}$  absorption band of water, an IR-spectrophotometric analysis method has been worked out that is applicable to mixtures containing 0.1–15% water. Dimethylamine and nitrosodimethylamine do not interfere, but methanol and ethanol would interfere if they were present in concentrations greater than 1%. Quartz cells measuring 1 cm were used for these tests. The results can be expressed by  $P = a + bA$ , where  $P$  represents weight percent of water in the mixture,  $A$  is 100 times the absorbance, and  $a$  and  $b$  are constants as follows (all data for 1-cm pathlength):

$$\text{N}_2\text{H}_4 \quad a = -0.053 \quad b = 0.1057$$

If the sample temperature differed by less than 2 K from that used during calibration, only minor deviations (<1%) were encountered. Oxygen must be excluded from the solutions to prevent autoxidation and the formation of additional water.

In an extension of this method, IR spectrophotometry was used for the analysis of both water at 1.9  $\mu\text{m}$  and aniline at 6.66  $\mu\text{m}$  [981]. The absorbance of the aniline peak at 6.66  $\mu\text{m}$  depends on the amount of water present. Before quantitative aniline results can be obtained, absorbance must be corrected for water content. This can be done by measuring the valley at 6.5  $\mu\text{m}$ . The method is applicable not only to binary water/hydrazine or aniline/hydrazine mixtures, but also to ternary hydrazine/water/aniline mixtures with up to 2.5% aniline and up to 7% water. The absolute error is  $\pm 0.05\%$  for either of the two contaminants. Best results were obtained with a cell with calcium fluoride windows and a 0.1-mm pathlength.

Atmospheric contaminants can be detected remotely without sample physical contact by **Light Detection And Ranging (LIDAR)**. Differential absorption LIDAR (DIAL) is a powerful remote sensing technique for the rapid detection of many toxic agents present in the atmosphere due to industrial and vehicular exhausts, rocket propellants, chemical warfare agents, and so forth. In a DIAL system, the concentration of the agent is determined from the ratio of strengths of return signals at two close-by wavelengths, known as online and offline wavelengths, such that the agent has strong absorption at the former wavelength and relatively weak absorption at the latter wavelength. A typical LIDAR system has a transmitter, receiver, microcontroller, and data acquisition and data processing units. A 50-cm-diameter Cassegrain telescope can be used to collect the backscattered signal. The transmitting and receiving telescopes, which are coaxially aligned, are mounted on gimbals. The receiving telescope is connected to the detector box that contains spectral filters and detectors. There are two detectors, one each for the detection of signals in the 2- to 5- $\mu\text{m}$  and 9- to 11- $\mu\text{m}$  regions.

Remote sensing of hydrazine, MMH, or UDMH vapors using a dual mini Transversely Excited Atmospheric (TEA) carbon dioxide laser DIAL system can detect 100 ppb hydrazine over a distance of less than 3 km (2 mi) [982–985]. The measurements involved LIDAR returns from a topographic target located 2.7 km

from the laboratory, but it was found during these experiments that atmospheric fluctuations were the major factor limiting the sensitivity of these measurements.

The  $^{12}\text{C}^{16}\text{O}_2$  laser can produce over 100 different discrete wavelengths between 9.1 and 11  $\mu\text{m}$  where there is very little interference from atmospheric water or carbon dioxide. Hydrazine, MMH, and UDMH have characteristic absorption bands in this regime, so their vapors in air can be detected by laser absorption or even by remote sensing techniques using LIDAR [986–989], also in combination with photoacoustic measurements [990]. The high-resolution laser radiation absorption cross sections of hydrazine, MMH, UDMH, and their oxidation products were determined first in order to assess the value of the laser techniques. In addition to IR absorption or LIDAR fluorescence, photoacoustic detection of hydrazines has been studied by pumping modulated laser energy into selected wavelengths of hydrazine vapors in a cell with a microphone and searching for sound waves with the same frequency [991]. Absorption of energy causes a temporary pressure pulse (=sound), which can be picked up by the microphone. With a laser output at 1 W/line, the photoacoustically detectable levels were 0.2, 0.3, and 0.3 ppb for hydrazine, MMH, and UDMH, respectively. In comparison, for simple long-path-length (100-m cell) absorption, the sensitivities would be “only” 70, 140, and 130 ppb, respectively. For LIDAR, remote sensing detection limits for the three hydrazines vary between 20 and 90 ppb. With polluted urban air as background, detection limits would be significantly worse. Most laser methods would suffer one to two orders of magnitude in sensitivity if hydrazines had to be detected against a background of urban atmospheric pollutants. Another IR method (so far used mostly for the detection of chemical warfare agents) relies on the blackbody radiation of buildings, rocks, or soil in the background of a radiometer-scanned area to provide a source of radiation. A hydrazine vapor cloud drifting between the background horizon and the observation site can be detected by its IR absorption [992].

Calculations for a 200-m-thick cloud of vapor showed that the minimum detectable concentrations at a distance of 5 km with a laser pulse of 200 mJ are 0.886, 1.166, and 1.737 ppm as the values of  $N_{\text{min}}$  for hydrazine, UDMH, and MMH, respectively. There are also upper limits where the incoming laser light is absorbed completely such that no energy is reflected [993].

Besides analyzing undecomposed hydrazine in various matrices, sometimes the chemist needs to analyze hydrazine decomposition products consisting of ammonia, nitrogen, and hydrogen, depending on the degree of ammonia dissociation in a catalytic reactor. Ammonia is the only IR absorber in this mixture. The ammonia dissociation is often a design variable in the design of rocket engines (see *Encyclopedia of Monopropellants*, chapter “Hydrazine Monopropellants”). Ideally, one would want an analysis method that gives an instant readout, instead of taking a grab sample and waiting several days for the results to come back from the lab. A non-dispersive infrared (NDIR) analyzer was used to monitor the ammonia and water content of hydrazine decomposition products in the gaseous state [994]. The analyzer was calibrated with two gas mixtures of known composition.

### 3.6.11.3 Spectrofluorescence Analysis Methods for Hydrazine

The fluorescence of solid or liquid samples excited with light of shorter wavelength can be very specific for certain hydrazine derivatives and is suitable for the detection of trace quantities, such as hydrazine derivatives on a thin-layer chromatography plate. The reagents that can form fluorescing compounds with hydrazine are 5-chlorosalicylaldehyde [995]; fluorescamine {4-phenylspiro-[furan-2(3H),1'-phthalan]-3,3'-dione} [729]; 3-(6-hydroxynaphthalenyl)-1-(4-nitrophenyl) prop-2-en-1-one [996]; 2,3-naphthalenedicarboxaldehyde [997–1001]; 1,2-naphthoquinone-4-sulfonic acid [1002]; and PDAB [1003].

### 3.6.11.4 Fluorescence Detection and Imaging of Hydrazine

Fluorescence detection of hydrazine and imaging of hydrazine distribution, even in living cells under the microscope, constitute a new analytical technique for hydrazine that is useful for tracing the path of hydrazines and the metabolic fate of hydrazine-derived pharmaceuticals in living organisms. The fluorescent dyes typically change their emission spectra after they are exposed to traces of hydrazine. Different techniques have been used, one called “turn on” fluorescence. Another technique is comparing emissions at two frequencies using a ratiometric method. Ratiometric fluorescence detection measures the ratio of fluorescence intensities at two different wavelengths. Very little comparable work has been done on any of the methylhydrazines. Many hydrazine-based pharmaceutical drugs metabolize and release hydrazine in the body. There is some justification for developing more sensitive analysis techniques to study the pharmacodynamics and toxicokinetics of hydrazine-based drugs and their metabolic products. But the worldwide use of hydrazine-based pharmaceutical drugs is declining over concern about hydrazine toxicity.

Fluorescence methods include rhodamine B [1004, 1005]; trifluoroacetyl acetate naphthalimide [1006]; cyanine dye derivative [1007, 1008]; dichlorofluorescein and resorufin acetate [1009]; 2-(4-((4-(benzo[d]thiazol-2-yl)phenyl)ethynyl)benzylidene)-malononitrile [1010]; carbazole based malononitrile [1011]; trifluoroacetyl acetate and coumarin [1012]; dibenzothiazole [1013]; 4-amino-1,8-naphthalimide [1014]; [4-phthalimide-N-(4'-methylcoumarin) naphthalimide] [1015]; resorufin [1016]; merocyanine 1,2,2,4-tetramethyldihydroquinoline [1017]; 4-bromobutyrate/fluorescein [1018, 1019]; azobenzene derivative-naphthalenediimide [1020]; coumarin-based fluorescent probe [1021]; 2-[4-(3,5-diphenyl-4,5-dihydro-pyrazol-1-yl)-benzylidene]-malononitrile [1022]; quinoline [1023]; condensation product of *N,N*-dimethylamino cinnamaldehyde with [1024]; combination of coumarin and benzopyrylium [1025]; coumarin and hemicyanine [1026, 1027]; tricyanofuran [1028]; naphthalimide and 4-hydroxynaphthalimide [1029]; 1,8-naphthalimide [1030, 1031]; pyrene- and anthracene-based compounds [1032]; 2-(9-ethyl-9*H*-carbazol-3-yl) isoindoline-1,3-dione [1033]; and chalcone cyclization [1034]. See also [1035–1040]. These methods have been used to detect and localize hydrazine in living mice and fish.

### 3.6.11.5 Chemiluminescence Analytical Methods

The chemiluminescent reaction of hydrazine oxidized by *N*-bromosuccinimide in the presence of dichlorofluorescein as a sensitizer has been used for the flow injection analysis of hydrazine solutions in a concentration range from  $1 \times 10^{-6}$  to  $5 \times 10^{-5}$  M [1041]. The detection limit was  $5 \times 10^{-7}$  M. A similar method used oxidation by hypochlorite and could detect  $10^{-5}$  M hydrazine [1042]. Some metal ions inhibited luminescence while others activated it. Another flow injection determination of hydrazine using a fluorimetric endpoint detection method involving the oxidation of hydrazine by thallium(III) had a detection limit of 20 ng/mL [1043].

Luminous oxidation with acidic permanganate was found to be usable for chemiluminescence determination of hydrazine and its derivatives [1044]. The sensitivity was high enough to determine hydrazine in workroom air. The linear range was  $3.0 \times 10^{-5}$  to  $1.0 \times 10^{-7}$  g/mL.

A chemiluminescence flow system for the determination of hydrazine was based on the enhancement effect of hydrazine on the chemiluminescence reaction between luminol and  $\text{BrO}^-$  in alkaline media [1045]. The oxidant  $\text{BrO}^-$  was online electrogenerated by constant current electrolysis, resulting in the elimination of the inconvenience of its instability. Hydrazine can be determined in the range of 0.01–10  $\mu\text{g/mL}$  with a detection limit of 0.003  $\mu\text{g/mL}$ . A complete analysis could be done in 1 min with a relative standard deviation of 3.7%. The method is suitable for the automatic and continuous online monitoring of low levels of hydrazine, for instance, in drinking and river waters.

The oxidation of hydrazine by potassium hexacyanoferrate(III) in alkaline luminol solution leads to chemiluminescence. This can be used to determine individual hydrazines using flow injection systems [1046]. The system has been successfully applied to the determination of hydrazine in air.

The oxidation of hydrazine by either sodium dichloroisocyanurate or trichloroisocyanuric acid in alkaline medium caused chemiluminescence and the emission intensity was greatly enhanced if dichlorofluorescein was added as a sensitizer [1047]. The parameters for the determination of hydrazine were optimized and the optimized method yielded  $3\sigma$  detection limits of  $2 \times 10^{-7}$  to  $3 \times 10^{-7}$  M for hydrazine.

### 3.6.12 Mass and Ion Mobility Spectrometric Analysis of Hydrazine

Mass spectrometric analysis of hydrazines is used extensively for trace detection, for the identification of the effluent of chromatographic separations, for the study of kinetic mechanisms, or for the determination of molecular bond dissociation data. The detection of hydrazine in air by mass spectrometry based on the parent ion alone is difficult since both hydrazine and oxygen have a molecular mass of 32 atomic mass units (amu). To make the problem worse, methanol has the same amu. The compounds must be identified by their ionized fragments in addition to the parent ions. Because hydrazine and ammonia have identical breakdown products in the mass spectrometer

ion source, it is impossible to differentiate between ammonia-derived and hydrazine-derived amino radicals  $\text{NH}_2$ . This section summarizes some of the experimental techniques used in obtaining mass spectra for hydrazines. The ionization and appearance potentials of hydrazine molecule fragments are listed in Table 46 below. The ionization and appearance potentials of several alkylhydrazine molecule fragments are summarized in Table 37 in the chapter “Methylhydrazine.” These tables will be an aid to future investigators in the identification of  $m/e$  peaks.

**Table 46:** Summary of appearance potentials of hydrazine.

| Species                                      | Parent compound        | Appearance potential, eV | References |
|----------------------------------------------|------------------------|--------------------------|------------|
| $\text{N}_2\text{H}_4^+$                     | $\text{N}_2\text{H}_4$ | 10.07                    |            |
| $\text{N}_2\text{H}_4^+(2\text{B})$          | $\text{N}_2\text{H}_4$ | 10.64                    | [497]      |
| $\text{N}_2\text{H}_4^+(2\text{A})$          | $\text{N}_2\text{H}_4$ | 15.61                    |            |
| $\text{N}_2\text{H}_4^+(2\text{B}2\text{A})$ | $\text{N}_2\text{H}_4$ | 16.66                    |            |
| $\text{N}_2\text{H}_4^{+*}$                  | $\text{N}_2\text{H}_4$ | 24.5                     | [496]      |
| $\text{N}_2\text{H}_4^{+**}$                 | $\text{N}_2\text{H}_4$ | 30.0                     |            |

Some of the appearance potentials were determined by photoelectron methods and not by electron impact ionization in a mass spectrometer. A very useful summary was published on the mass spectrometry of inorganic radicals, including those formed by hydrazine decomposition [349].

In many instances in a mass spectrometer, not only is the hydrazine molecule dissociated, but the ion is also left in a state of excitation from which a photon may be emitted. The state of excitation is indicated either by letters in parentheses or by an asterisk following the formula of the ion. The calculated ionization potential of  $\text{N}_2\text{H}_4$  is 7.54 eV, in agreement with experimental data [425].

Most mass spectrometric investigations of hydrazine used electron bombardment for sample ionization. A gentler ionization method that causes less random fragmentation can be achieved by field ionization [1048, 1049] or photoionization [356, 495]. A comparison of the fragmentation patterns is given in [22], Table 5.20, Section 5.4.1.2. The hydrazinium dication is well known in liquid acidic solutions, but less well characterized in the gas phase, where it has shown surprising stability [1050].

It is very difficult to obtain an accurate quantitative analysis of argon-diluted hydrazine/ammonia mixtures by mass spectrometry because varying amounts of hydrazine hang up in the inlet system of conventional mass spectrometers [1051]. Hydrazine and ammonia can be separated from the permanent gases by first condensing them in a cold trap at 119 K. Subsequently, after analyzing the gases passing through the cold trap, the cold trap is thawed, and hydrazine and ammonia are quantitatively decomposed into the elements in a glow discharge. The hydrogen : nitrogen ratio of the decomposition products then gives the hydrazine : ammonia ratio in the condensate.

Mass spectrometry is well suited for the analysis of volatile contaminants in liquid hydrazine. Various contaminants have been observed in this manner but could not always be identified. In hydrazine that had been dried and distilled over calcium hydride, a contaminant at  $m/e = 60$  has been observed that could not be removed by passing the vapor through molecular sieves at 340 K [353, 1052].

### 3.6.13 Electron Spin Resonance Analysis of Hydrazyl Free Radicals

ESR analysis is widely used to identify free radicals, the short-lived ones involved in the decomposition of hydrazine and the stable ones obtained by dissociation of tetraphenyl hydrazine and other aromatic hydrazines. Hydrazyl free radicals were identified by ESR in the decomposition of a hydrazino nitroso ferrate complex in aqueous solution [1053] and during autoxidation of hydrazine in solution [1054].

### 3.6.14 Trace Analysis of Hydrazine

#### 3.6.14.1 Trace Analysis of Hydrazine in Water

The sensitivity of analytical methods for the analysis of hydrazine in environmental water samples can be improved by adsorbing the hydrazine-PDAB aldazine onto solid sorbents and then extracting it with hydrochloric acid [1055]. The limit of detection for the method was 0.2 mg/L. The method was used to determine hydrazine in freshwater, seawater, and wastewater.

Hydrazine concentrations in solutions used in the PUREX nuclear fuel reprocessing process can be measured remotely by fiber optic cables where the exposed section of the bare fiber is coated with a gel containing PDAB [1056, 1057]. A similar fiber optic sensor used fibers coated with 4-nitrobenzaldehyde in a gel of polyethylene oxide [1058].

#### 3.6.14.2 Analysis of Trace Contaminants in Hydrazine

Many applications of hydrazine require a very pure product and will not tolerate contaminants in the hydrazine used. Examples of such applications are the use of hydrazine as reductant in the production of laser crystals or the use of hydrazine as a monopropellant in rocket engines on long-term missions. Hydrazine that has been purified to meet strict purity requirements will have to be analyzed for trace contaminants before and after the purification process. Contaminants can be organic or inorganic in nature. The most bothersome contamination caused by the absorption of atmospheric carbon dioxide and leading to hydrazinium carbazate probably should be classified as an inorganic contaminant, although other carbonic acids are considered organic compounds. The military propellant specifications contain detailed methods for the analysis of trace contaminants in hydrazines and hydrazine blends. This section contains a few additional methods not yet covered in the MIL-SPEC.

**Chloride.** Excess hydrazine must be removed by reaction with 3% hydrogen peroxide before chloride can be determined with the diphenylcarbazone/mercury(II) nitrate or the mercury(II) thiocyanate spectrophotometric method [485].

Chloride is often determined in concentrated NVR instead of liquid hydrazine because this eliminates the interference by hydrazine and affords orders-of-magnitude improvements of detection limit. Because of the volatility of hydrazinium chloride under conditions of NVR determination, some chloride-free AR-grade sodium hydroxide must be dissolved in hydrazine prior to distillation. Samples of monopropellant-grade hydrazine were spiked with various levels of standard aqueous hydrogen chloride to measure percent recovery by this method [1059]. Two NVR analysis methods were compared using three different chloride determination techniques. The major source of variation in chloride recovery from hydrazine appeared to be due to the mechanical loss of material during the open beaker evaporation step of one NVR method.

**Fluoride.** An electrochemical method was used to analyze trace fluoride in hydrazine [1060]. Other than this, there is no standard test method for the analysis of fluoride in hydrazine. Several colorimetric methods for fluoride in water do not work in the presence of hydrazine interference [1061].

**Total Carbon.** Instead of specifying individual limits for carbon dioxide and organic contaminants in hydrazine, some agencies have begun specifying limits on total carbon in hydrazine. Early vintage (1955) hydrazine was allowed to have up to 1.5% aniline and hydrocarbon (typically *n*-heptane remaining from the distillation process). Total carbon was analyzed initially by combusting the sample in air over a roll of oxidized copper wire gauze in a 25 × 910 mm Vycor tube [673]. The carbon dioxide was absorbed in a U tube filled with Ascarite and Anhydrone and weighed in the same manner as in an ordinary CH elementary analysis. Because relatively large samples (up to 1.4 g) were used, the weighing errors could be kept small, and good accuracy was achieved. A more recent version of a combustion technique for determining total carbon content in hydrazine also uses large samples (1 cm<sup>3</sup>) of hydrazine and combusts them in a stream of oxygen over a copper oxide catalyst at 1123 K [1062]. The carbon dioxide in oxygen (and water) is collected in a 16-L tank at 340 kPa and analyzed by an IR method. The precision of this method is ±20% in the 20- to 40-ppm total carbon range.

Total carbon analyzers and total organic carbon (TOC) analyzers that were developed mostly for water analysis can be used for dilute, nonflammable hydrazine solutions. EPA methods analyze one sample directly, the other sample after dispelling all mineral carbonates by acidification with a non-volatile acid. TOC is calculated as the difference between the two numbers. Organic contaminants that were leached from container materials (bladders, diaphragms) used for storage or expulsion of hydrazine can be determined by this method. Organic contaminants carried over from hydrazine hydrate that was made by the ketazine or hydrogen peroxide method and then dehydrated to make anhydrous hydrazine can be analyzed by this method.

**Carbon Dioxide.** Carbon dioxide absorption is a problem not only with hydrazine but also alkylhydrazines and resulting in corrosion problems. Methods recommended for the analysis of CO<sub>2</sub> in alkylhydrazines can probably be used for hydrazine itself as well [1063, 1064].

**Trace Metals.** Trace levels of titanium that has been leached from the wall of titanium tanks during long-term storage of hydrazine can be determined by atomic absorption spectrophotometry (AAS) following flash evaporation of the hydrazine and re-dissolving the residue in 0.2% nitric acid [1065]. The AAS spectrophotometer used a graphite furnace lined with a coating of pyrolytic graphite, in which a 10-μL sample was dried at 423 K, charred at 2070 K, and atomized at 3070 K. The titanium spectral line used for absorption was the one at 365.4 nm. The method is sensitive down to 2 ng/μL = 2 mg/L = 2 ppm. The average error in this range was 15%. The same method should be applicable to a wide range of other trace metals in hydrazine. Unfortunately, the flash evaporation is associated with a (relatively constant) loss of material that must be determined in a separate experiment prior and in addition to calibration samples. In the example given, 12 ng Ti was lost, and this number had to be arbitrarily added to the results on each sample. Elevated metal losses during the charring step may occur in the presence of fluoride since most fluorides are volatile.

High levels of cadmium were discovered in some samples of high-purity hydrazine. Cadmium may have leached from some of the equipment in which hydrazine is dehydrated and distilled at the manufacturer. The highest level of cadmium detected in hydrazine was 0.38 ppm, and it caused clogging in cavitating venturi [269].

Excessively high alkali metal concentrations in either the oxidizer or the fuel could lead to high ionization in the exhaust and radio-frequency interference in plumes of bipropellant missiles, launch vehicles, and spacecraft. A highly ionized plume will shield radio waves. Potassium and sodium in typical Aerozine-50 was analyzed by AAS and found to be on the order of 0.07–0.18 ppm Na and 0.82–1.13 ppm K [1066]. There is no MIL-SPEC specification limit for alkali metals in bipropellant fuels. Similar tests were conducted on sodium and potassium in UDMH or NTO [1067].

**Silicon.** Organic silicon compounds leached from elastomers (diaphragms, bladders) immersed in hydrazine in positive expulsion tanks can be analyzed by IR in a spherical chamber with multiple reflections [1068].

### 3.6.14.3 Trace Analysis of Hydrazine in Air

Because the olfactory threshold for hydrazine vapor is above the concentration at which permanent damage can be caused by continued hydrazine vapor inhalation, it is very important to monitor workplaces with sensitive analytical devices. One cannot rely on the human sense of smell alone to receive a warning when dangerous hydrazine concentrations are exceeded. This applies to hydrazine itself as well as many volatile hydrazine derivatives. The methylhydrazines have a more pronounced (“fishy”) odor and are more readily detected than hydrazine itself.

The olfactory threshold for hydrazines is discussed in Section 9.12. What is now needed are analytical methods that are more sensitive than our noses and provide a more quantitative answer. The sensitivity requirements for hydrazine detection instrumentation are inevitably tied in with the TLVs and emergency exposure limits (EELs) established by various government agencies for the protection of workers inside and the general public outside of factories and rocket test sites. The two sets of numbers seem to “leapfrog” each other where the government regulators are reasonable enough not to establish limits so low that they cannot be verified but nevertheless often set them so low that each lowering constitutes a new challenge to the instrument industry. The limits for hydrazines have been lowered twice by several orders of magnitude in the two decades preceding the 1990s. Therefore, the instrument industry was constantly struggling to come up with instruments that could reliably detect the new TLVs or even fractions of the new TLVs to provide some level of confidence or to be prepared for the next imminent lowering of the TLV (justified or not). To the uninvolved bystander it sometimes looked as if the availability of more sensitive detection methods (more sensitive than the current TLV) spawned a new round of calls from the occupational hygiene community for additional lowering of the TLVs and EELs. The cost:benefit ratio of those actions was never shown, and nobody knows how many lives have been saved or extended.

The words *sensor* and *detector* can be used interchangeably and refer to the part of the system that is exposed to vapors. A *monitor* consists of a sensor or detector connected to some electric circuitry that can be adjusted to a certain threshold above which an alarm will sound to alert the workers. A single central monitor can interrogate many remote sensing stations in sequence by a rotary switch. A recording monitor keeps a continuous and permanent record of the concentration profile as a function of time.

Detectors and monitors for hydrazine and hydrazine derivatives must be both sensitive and specific. Unfortunately, many detection methods that are sensitive to hydrazine(s) will also respond to the presence of other vapors in air. Many sensors respond to ammonia. Ammonia is a typical hydrazine decomposition product but is also produced by many other biological processes (e.g., in a horse stable or outhouse). Many hydrazine sensors suffer interference (false readings, low readings) from the presence of other contaminants in air. Some are affected by the level of humidity. Many launch sites are in coastal areas where the humidity is always high.

In addition to detectors and monitors that sound an alarm if a preset threshold concentration is exceeded, it has become increasingly important to develop instruments that give a continuous recording of hydrazine concentration on chart paper or magnetic tape. Such stationary instruments are recommended for production and test installations using hydrazines to show compliance with OSHA regulations at places of employment and to protect the employer from later liability suits.

The main application of these instruments is to monitor work areas where personnel are potentially exposed to and may inhale hydrazine vapors. Additional applica-

tions for these instruments are leak detection in propellant storage areas, in spacecraft or submarines, and in test installations. Other needs are the monitoring of propellant clouds released from controlled spill tests in uninhabited areas to study plume dispersion and atmospheric decay of propellant vapor clouds [1069].

Progress in the area of toxic missile propellant vapor detection has been significant in recent decades, necessitated by the concern about a wide range of adverse effects caused by hydrazines. In the US, most of the work performed on propellant vapor detectors was aimed at the detection of the more volatile MMH, which was used in the Space Shuttle Orbital Maneuvering System (OMS) and in the Minuteman and Peacekeeper intercontinental ballistic missiles (ICBM) third stages stored in missile silos. Relatively little work has been conducted specifically on the less volatile hydrazine. The use of UDMH or Ae-50 in the US has been phased out. Surveys of missile propellant vapor detectors have been published in the literature from time to time and are summarized in Table 47. Some candidate analytical methods included in these surveys never advanced past the experimental stage and did not result in commercially viable products. Surveys of commercially available instruments are quickly outdated because some manufacturers went out of business and others changed names or were bought out by or merged with competitors.

A review was conducted of commercially available sensors that are able to detect hydrazine or MMH concentrations from as low as 10 ppb up to several parts per million and that are most commonly used as either leak detectors or personnel monitors [1083].

A wide range of chemical interactions between hydrazine and organic reagents have been reviewed for their adaptability to microsensors for hydrazine vapors [1084]. The microsensors generally consist of a physical probe and a coating that has specific affinity toward hydrazines. Some of the microsensors now tested with hydrazine(s) were derivatives of existing sensors originally intended for the detection of toxic chemical warfare agents. The sensing principles considered were (1) surface acoustic waves on piezoelectric crystals, (2) optical wave guides, and (3) chemiresistors. The optical waveguide methods involve color-changing reactions. The reactions suitable for specific sensing of hydrazines include those of (1) aldehyde and ketone carbonyl compounds, (2) nucleophilic aromatic displacements, (3) organic compound and metal ion redox reductions, and (4) organic dyes. It has been proposed to study second-derivative spectrometry and ion cluster spectrometry as a means for continuous measurement of hydrazines in concentrations down to 0.05 ppm.

Wet flow injection/amperometric analysis methods where hydrazine vapor in air first had to be absorbed into aqueous solutions were compared to both surface acoustic wave (SAW) devices and quartz crystal microbalances (QCMs) with the objective of being able to detect hydrazine vapor at concentrations below 1 ppm [1085].

**Table 47:** Historical summary of publications on hydrazine(s) vapor detector technology.

### 3.6.15 Hydrazine in Air Sampling Methods

The following sections are subdivided by active and passive sampling methods. By *active* we understand that the system needs a pump to force air through the apparatus. *Passive* samplers or badges depend on the diffusion of ambient air and air movements (often the draft of the working person moving through the working environment). Passive methods have the advantage that they do not require a portable power source, but they are probably not as accurate as active samplers. Other systems to subdivide a chapter on trace analyzers would be by *direct reading* and *non-direct-reading* instruments.

There are passive and active analyzers in both groups. A passive analyzer can be direct reading if the color change of a reagent button alarms the person wearing and looking at it. Non-direct reading instruments are usually samplers that have to be taken to a laboratory at the end of the work period, where the samplers are extracted, and the extract is analyzed to obtain a number. Another approach to subdividing this section would be by portable and stationary instruments. All personal samplers/detectors/badges must be portable by definition. The instruments must be small enough that they do not prevent propellant technicians from doing their job.

The least expensive, most accurate, but more manpower-intensive method of sampling air in contaminated areas is by bubbling a known amount of air through dilute sulfuric acid (0.1M) in impingers (bubble flasks), followed by analysis of the dissolved hydrazinium sulfate in aqueous solution. Many different analysis methods are available for that step of the process.

The efficiency of impingers may depend on the design of the apparatus (glass orifice, fritted glass plate diffuser). Concerns have been raised over the repeatability of air analysis with impingers depending on the geometric variations (orifice size, liquid depth, air flow rate) of the equipment. In an effort to correlate variances in the geometric parameters of “identical” (same part number) impingers to the repeatability of chemical analyses,  $N_2H_4$ , MMH, and UDMH were used as test vapors. Nominal concentrations of 80 ppb  $N_2H_4$ , MMH, and UDMH were generated. Ultimately, it was found that orifice size did not have a significant effect on the repeatability of the analysis [1086]. By hooking up two impingers in series, it was shown that any difference in the measured vapor concentrations observed between various impingers was not due to vapor breakthrough from the first impinger.

Instead of air sampling with liquid absorbents, usually with dilute acids in impingers (“bubblers”), it is more practical to use solid absorbents, which can consist of inert granular ceramic carriers impregnated with an acid, held in sampling tubes through which air is drawn at a controlled rate and for a known length of time. Some of these solid sorbent tubes and the subsequent spectrophotometric analysis capture hydrazine as well as MMH and UDMH [1087]. With this particular method, the relative error of measurement was less than 17%, and the recovery rate was better than 80%. Hydrazine in air was collected in a tube filled with 2,4-pentanedione and the 3,5-dimethylpyrazole thus formed was extracted with methanol and analyzed by means of GC-MS [1088].

### 3.6.15.1 Surveys and Laboratory Evaluation of Commercially Available Analyzers

In trying to decide which instrument to buy for a specific monitoring application, it is difficult to maintain an up-to-date “Buyer’s Guide” for hydrazine monitoring instruments. Unfortunately (fortunately if improvements are incorporated into new instruments), the market is constantly changing, which means this section will be one of the first sections of this book to become obsolete. One may still have to conduct one’s own market survey or even a side-by-side laboratory or field evaluation of several in-

struments to find the one that suits specific needs. An introduction to hydrazine vapor monitoring instruments was given in [1089] with more than 100 references to the literature but that is now only of historical interest. Section headings in that summary were

- Calibration Methods and Vapor Generation Chambers
- Materials Selection to Avoid Sampling Losses due to Wrong Materials for Air Sampling Tubing
- Colorimetric Detectors and Monitors
- Passive Personal Dosimeter Badges (Direct Reading)
- Actively Pumped Gas Detector Tubes and Paper Tape (Direct Reading)
- Gas Detector Tubes
- Impregnated Paper Analyzers
- Personal Passive Samplers (Not Direct Reading)
- Personal Active Samplers and Solid Sorbents (Not Direct Reading)
- Impinger Methods – Wet Chemistry (Not Direct Reading)
- Active Recording Detectors (Direct Reading, Portable, but not Lapel-Mounted)
- Fiberoptic-Colorimetric and Waveguide Methods
- Noncolorimetric Detectors and Monitors
- Ionization and Photoionization Chambers for Detection of Hydrazines
- Mass Spectrometric and Ion Mobility Detection Methods
- Electric Conductometric and Differential Temperature Detectors
- Optical Direct IR Absorption Methods for Detection of Vapors
- Open-Path IR Absorption Methods, also with Lasers as the Light Source
- Laser Photoacoustic Spectroscopy
- Laser Raman/Surface-Enhanced Raman Spectroscopy (SERS)
- Optical-Emission Chemiluminescence Detectors and Monitors
- Electrochemical Potentiometric Detectors and Monitors
- Thin-Film Redox Electrodes as Hydrazine Vapor Detectors
- Coated Carbon and Graphite Electrodes in Hydrazine Vapor Detectors

That summary needs to be updated from time to time. In the following pages, only a few of the sections listed above are expanded and updated, mostly with publications published after the year 2000. No assurance is given that this review is complete, and it would require a substantial effort to keep it up to date. In this volume, *Encyclopedia of Liquid Fuels*, the chapters “Methylhydrazine” and “Dimethylhydrazines” contain a similar summary of instruments for the detection of MMH or UDMH vapors in air. Some of those instruments will also respond to hydrazine itself.

As part of an effort to upgrade the sensor technology background information, NASA requested information from a total of 27 manufacturers of portable multi-gas instruments [1090]. A set of criteria was established to determine which vendors would be selected for laboratory evaluation. Each of the 27 manufacturers of multi-gas analyzers was sent a copy of the criteria and asked to fill in the appropriate information

pertaining to their instrumentation. Based on the results of the sensor criteria worksheets, a total of 9 vendors out of 27 surveyed manufactures were chosen for evaluation.

### **3.6.15.2 Calibration Methods and Vapor Generation Chambers**

An instrument setup for calibrating model MDA 7100 paper tape cassette hydrazine detectors in the USAF inventory consisted of a Kintek 491 permeation tube reference gas generation system, a humidifier/mixer system (which combines the dry reference hydrazine gas with humidified diluent or carrier gas to generate the required humidified reference for calibrations), and a gas sampling interface [1091]. The Kintek reference gas generation system itself was periodically calibrated using coulometric titration to verify the hydrazine concentration of the sample atmosphere in the interface module. The Kintek reference gas was then used to calibrate the hydrazine monitors. Thus, coulometric titration is only used to periodically assess the performance of the Kintek reference gas generation system and is not required for hydrazine monitor calibrations. One advantage of using coulometric titration for verifying the concentration of the reference gas is that it is a primary standard (if used for simple solutions). The report also contains a description of the hydrazine calibration system used by the MDA 7100 instrument's manufacturer, Zellweger Analytics.

### **Material Selection to Avoid Sampling Losses due to Wrong Choice of Materials for Air Sampling Tubing**

Many of the McEwen and Vernot animal inhalation toxicity data in the 1980s are invalid due to long sampling lines made from absorbent plastics. A single central hydrazine analyzer served several animal exposure chambers and was connected to those chambers with long, thin plastic hoses. Much of the hydrazine leaving the exposure chambers never arrived at the analyzers due to absorption into and diffusion through the plastic. As a result, the animals were exposed to much higher hydrazine concentrations than what was read on the analyzers and reported in the literature.

### **3.6.15.3 Passive Personal Dosimeter Badges (Direct Reading)**

An automated system for reading the exposure levels of personal dosimeters worn by personnel at rocket test sites and archiving exposure data for subsequent evaluation has been developed [1092, 1093]. The reading of personnel dosimeter badges for exposure to potentially harmful vapor concentrations of hydrazines is usually performed visually at the end of the work shift by comparing the color developed by the badge with a calibrated color comparator chart. The badge reader also stores bar-code data unique to each badge, as well as bar-code information on the user, as part of the permanent badge record.

A single-spot dosimeter for real-time, colorimetric detection of hydrazine in air mounted on a passive badge consisted of a dosimeter card containing a vanillin so-

lution coated on a thin paper substrate [1094]. The active patch consisted of a thick cellulose substrate coated with a vanillin solution. When placed in a plastic sample holder attached to a personnel pump, up to 5 L/min could be drawn through the active badge substrate. The vanillin hydrazone formed in the reaction was yellow. The spot color intensity was proportional to the dose. When exposed passively to hydrazine, the experimental detection limit was  $20 \text{ ppb} \times \text{h}$ . Extrapolated results indicate that a detection limit of  $5 \text{ ppb} \times \text{h}$  for long sampling periods should be possible. RH effects on badge response were minor. High humidity enhanced the color development on the vanillin badge, while low humidity had no effect on badge response.

A two-spot passive dosimeter badge developed and tested by the Naval Research Laboratory (NRL) and GeoCenters was extensively used at NASA Kennedy Space Center (KSC) for personnel monitoring of  $\text{N}_2\text{H}_4$  and MMH. This badge, manufactured by Bacharach (former GMD), utilizes two chemistries: PDAB and vanillin impregnated on filter paper. A color must be observed on both spots of the badge as verification of the presence of toxic vapors. In the case of both  $\text{N}_2\text{H}_4$  and MMH, the PDAB spot turns orange, while the vanillin turns yellow. There was no observable color when the badge was exposed to UDMH vapors. The minimum detectable doses of  $\text{N}_2\text{H}_4$  and MMH for this badge were  $25 \text{ ppb} \times \text{h}$  and  $50 \text{ ppb} \times \text{h}$ , respectively. Cross interferences of several organic and inorganic substances known as normal satellites of hydrazines, including up to 25 ppm ammonia, were examined. None of the tested substances showed any effect on the performance of the hydrazine systems. The hydrazine and MMH systems use the same sensor. This sensor is 10 times more sensitive to hydrazine and MMH than to UDMH.

The K and M Environmental Corporation has developed a simple, direct-read, one-spot passive badge for all three hydrazines ( $\text{N}_2\text{H}_4$ , MMH, and UDMH) [1095]. The badge operates on the same principle of diffusion. The presence of  $\text{N}_2\text{H}_4$ , MMH, or UDMH is indicated by the formation of a color change in the shape of an exclamation mark inside a triangle on the front of the badge. Unlike the Bacharach/GMD/NRL badges, which were made from impregnated filter paper, the K&M sensors are fabricated from a uniformly coated indicator layer placed on an inert surface. This alternative construction causes the sensor to be more sensitive and consistent in its color formation. The minimum detectable levels (MDLs) for  $\text{N}_2\text{H}_4$ , MMH, and UDMH were 4.5, 6, and  $10 \text{ ppb} \times \text{h}$ , respectively. Personal dosimeters for hydrazine or MMH are also available from DOD Technologies under the ChemLogic trade name.

### **Actively Pumped Paper Tape (Direct Reading, Portable or Stationary)**

A common feature of continuously operating vapor sensors available from several instrument suppliers is a spool of reagent-impregnated paper tape that is held between two tubes through which air flows at a known rate. The paper tape is advanced at certain time intervals and color changes are measured in reflected light. The discoloration is proportional to the concentration of toxic agent in the air. The impregnating reagents that have been used by various instruments include molybdatophosphoric

acid [937, 1074], PDAB, and potassium tetrachloroaurate [1096]. Instruments of this type were (are) made by MDA Scientific, later acquired by Zellweger Analytics, currently operated by Honeywell Analytics. This includes the CM4 Chemcassette, SPM Flex, and ChemKey TLD Toxic Gas Detectors.

One of the first paper tape instruments was the AutoStep hydrazine analyzer made by GMD, a company that was later absorbed by Bacharach [1097]. The GMD MK-2 is a microprocessor-controlled instrument with direct liquid crystal display meter readout and full data storage facilities. Some of the performance requirements established for the detector were an accuracy of  $\pm 1$  ppb tested at 10 ppb, linear range of 0 to 400 ppb, zero and span drift of  $\pm 2$  ppb in 4 h, response time of less than 4 min to 90% tested at 10 ppb, error due to temperature change from 273 to 313 K (0 to 40 °C) at 45% RH within  $\pm 20\%$ , and error due to humidity change from 10 to 80% within  $\pm 25\%$ . Evaluation tests, other than the RH test, were performed using hydrazine, MMH, and UDMH vapors ranging from 1 to 400 ppb at 298 K (25 °C) and 45% RH.

### Actively Pumped Gas Detector Tubes and Badges

An MSA ProLite Turbo personal sampling pump was used at NASA KSC to draw air samples through filter paper treated with a mixture of vanillin and 0.5% phosphoric acid [1098]. The pump was orificed to draw 1 L air/min. At this flow rate, the TLV (1992) threshold of 10 ppb MMH could be detected within 10 min. The paper disc was held between two O-rings in a Lexan housing to which the suction hose of the pump was connected. This is essentially like the passive vanillin badges, except instead of relying on convection and movement of the personnel wearing the badge, a constant air flow is drawn through the paper similar to the portable or stationary recording instruments. The colors were read by inserting the card from the badge into a Minolta CR-200 Chroma color-light meter.

An active hydrazine vapor sampler was developed to detect vapors of hydrazine and MMH in air at ppb concentration levels [1099]. The sampler consisted of a commercial personal pump that draws ambient air through paper tape treated with vanillin (4-hydroxy-3-methoxybenzaldehyde). The paper tape is sandwiched in a thin cardboard housing inserted in one of the two specially designed holders to facilitate sampling with two 1.5-cm-diameter windows in the front and back. Contaminated air reacts with vanillin to develop a yellow color. The intensity of the color is proportional to the concentration of hydrazine or MMH. This device can detect 10 ppb in less than 5 min.

An active vanillin badge patch consists of a thick cellulose substrate coated with a vanillin solution [1094]. When placed in the sample holder attached to a personal pump, flow rates up to 5 L/min can be drawn through the active badge substrate. The detection limit for hydrazine at a flow rate of 5 L/min was below 100 ppb.

The color transition temperature of some liquid crystal chemicals changed after the chemicals had been exposed to hydrazine, UDMH, or nitrogen dioxide at concentrations of less than 10 ppm. Attempts have been made to develop a dosimeter badge based on this reaction [1100].

### Personal Passive Samplers (Not Direct Reading)

A badge personal dosimeter has been adapted to hydrazine monitoring, and the results of the dosimeter were compared to results obtained with GC methods with prior derivatization with furaldehyde [1074, 1101]. The best results were obtained with hydrazine and PDAB, but analysis of UDMH was more difficult. The badge contained a diffusion-controlled absorption element containing 5N  $\text{H}_2\text{SO}_4$  on non-woven porous polypropylene sheets or firebrick granules. The absorbed hydrazine, bound as hydrazinium sulfate, was subsequently extracted and analyzed colorimetrically with PDAB. Linear response in the range 0.1–10 ppm was demonstrated with a statistically significant number of samples. As an alternate method, derivatization with furaldehyde, followed by GC analysis, was attempted with moderate success for hydrazine alone. Exposed dosimeters could be stored refrigerated for up to 7 d without loss of hydrazine.

#### 3.6.15.4 Impinger Methods – Wet Chemistry (Not Direct Reading)

For the analysis of hydrazine in air at places of employment in the UK, the recommended method is sampling either onto acid-coated glass fiber filters followed by solvent desorption or directly into modified impingers with dilute sulfuric acid, followed by analysis by liquid chromatography after derivatization with benzaldehyde [1102].

#### 3.6.15.5 Fiber Optic-Colorimetric and Waveguide Vapor Detection Methods

It is more reliable to have a multitude of remotely operating colorimetric sensors out in the field and connect them via fiber optic cable to a central processor. The task is to make the “multitude of sensors” cheap enough that an entire multi-node network can be set up to spatially monitor, for instance, a drum yard where hydrazine is stored.

An optical waveguide sensor using oxazine perchlorate dye initially intended for ammonia detection has been modified to detect hydrazine vapors [1103, 1104]. It was hoped that this system would be reversible, but initially reversibility had been demonstrated only for ammonia and not for hydrazine. Even if the chemical reaction and color change at the end of the fiber optic cable was irreversible, there would be potential applications for such a remote sensing network.

Distributed multi-site fiber optic chemical sensors for real-time monitoring of hydrazine, MMH, and UDMH down to the 10 ppb concentration level based on evanescent wave interaction at the fiber optic surface using triphenylmethane dyes immobilized onto the surface of silica fiber may be susceptible to other amine or ammonia vapors [1105].

Fiber optic chemical sensors were developed for the remote detection of hydrazine propellant vapors in a network of sensor stations. The sensors contained a color-changing indicator (phosphomolybdic acid) that reacted selectively and irreversibly with hydrazines to yield chemical compounds that absorb laser light launched into a fiber optic network. The sensors were fabricated by dispersing the reagent within either a porous cladding or a porous gelled distal end coating. Remote

field-scale detection of hydrazine vapor in regime of a few hundred ppb  $\times$  min integrated dose was demonstrated with a network that was approximately 1 km in length and used a low-power (10-mW) diode laser [1106–1109]. Hydrazine detection fiber optic dosimeters were tested for periods of up to 3 months at Cape Canaveral Air Force Station (CCAFS) to determine the effect of the local environment on lifetime and sensitivity [1110]. The dosimeters were deployed at a diverse group of sites, including fuel, oxidizer, and hydrocarbon fuel storage and transfer locations. In addition, a group was set aside in a sealed enclosure for control purposes. The dosimeters were retrieved at monthly intervals and exposed to measured doses of hydrazine vapor to determine the effects of the field exposure on their hydrazine response. The analysis indicated that 90% of the exposed dosimeters were able to sense hydrazine at a dose detectivity of less than 15 ppb  $\times$  h, a value that meets the current hydrazine sensing requirement. The reaction of hydrazine with phosphomolybdic acid is irreversible, but similar fiber optic sensors were evaluated that contained 2,4,7-trinitrofluorenone, an electron acceptor compound that selectively formed chemically reversible, colored intermolecular charge transfer complexes [1111].

Evanescent wave fiber optic sensors for hydrazine, MMH, and UDMH capable of detection below 10 ppb were prepared by removing the cladding from commercial multi-mode fibers and coating the exposed core with a hydrazine-sensitive triphenylmethane dye immobilized in an inert polymer matrix, typically poly(vinyl chloride) [1112]. Triphenylmethane dyes bleach reversibly in the presence of hydrazines, enabling colorimetric sensing. The linear dynamic range was typically 0–300 ppb and the overall dynamic range was up to ca. 5 ppm. Sensors optimized for hydrazine were only as much as a factor of 45 less sensitive to MMH and UDMH, suggesting that the sensor film would require optimization for each analyte. Saturation response and relaxation times were on the order of 5–8 min, but measurable signals for 10 ppb hydrazine could be obtained in under 30 s.

A fiber optic hydrazine and NO<sub>2</sub> sensor used an acid-base indicator that underwent color changes depending on which gas was present [1113, 1114]. Bromothymol blue bromocresol green mixture (1/1) in hydrogel (1/1) produced a blue-green indicator for hydrazine and/or NO<sub>2</sub>. The sensor was tested several times over a period of 8 weeks, and the response was consistent when exposed to 52 and 18 ppm hydrazine or 400 and 200 ppm NO<sub>2</sub>.

A hydrazine fiber optic reversible sensor used commercial silica fibers and a pentacenediquinone (PDQ) and polymer mix, with an index of refraction adjusted to closely match that of silica as an active sensing material replacing the cladding of a silica core optical fiber [1115]. The optical signal passing through this modified cladding-type fiber sensor exhibited a reversible intensity change in the presence of hydrazine at different concentrations. The sensor contained a PDQ/organic compound mix as an active sensing element in a 5-cm-long modified cladding fiber sensor [1116]. The refractive index of this modified cladding was adjusted to 1.492 to closely match that of the silica fiber core. When the PDQ reacted with

hydrazine, oxygen atoms from the PDQ were replaced by a molecule of hydrazine. This replacement resulted in a significant increase in the absorption spectra of the mix, specifically at wavelengths between 1331 and 1430 nm as well as at 1550 nm.

### 3.6.15.6 Ionization and Photoionization Chambers

Other methods investigated for possible use in hydrazine or UDMH vapor detection and monitors include ionization chambers with  $^{90}\text{Sr}$  isotope as  $\beta$ -radiation source [1117]. Photoionization by UV light can be a very sensitive detection method for contaminant levels from a few ppb to 1000 ppb with decent linearity over the entire range, which is a very desirable feature. Photoionization detectors (PIDs) are often used in the effluents of gas chromatographs after a mixture of chemicals has been first separated. One of the unique properties of hydrazines in comparison to other flammable or toxic vapors is the low ionization potential in comparison to other photoionizable molecules. However, without prior separation by GC, the PID is not specific to hydrazines and has shown significant humidity interference and occasional lamp window contamination.

Commercially available photoionization gas detectors, mostly used for the detection of flammable gases, can be modified to detect hydrazines. Instruments of this type are made by RAE Corporation with brand names such as ToxiRAE, UltraRAE, and MultiRAE, some portable ones even feature wireless transmission of results to a central receiving station. In the UltraRAE, an 8.1-eV lamp was suggested for hydrazine in order to screen out as many interfering compounds as possible.

A xenon lamp with photons of 8.44 eV selectively ionizes only species with ionization energies below this level [1118]. Hydrazine has an ionization potential of 8.4 eV, MMH 8.0 eV, and UDMH 7.8 eV. Many organics, such as amines, will, unfortunately, interfere. The non-selectivity disadvantage of the PID can be overcome by combining a PID with a modulated ON/OFF or IN/OUT decomposition or absorption filter in the sample inlet [1119].

A photoionization gas sensor for hydrazines that can also measure other volatile organic compounds and other gases in concentrations from sub-ppb to 10000 ppm was capable of giving real-time readings and monitoring continuously [1120]. The design of a micro ionization chamber and signal detection circuits was integrated with a single-chip microcomputer. This instrument was portable and small and had high accuracy, fast response, and continuous operation capability.

### 3.6.15.7 Mass Spectrometric and Ion Mobility Detection Methods

A miniature mass spectrometer with a focal plane geometry was developed at the Jet Propulsion Laboratory [1121]. The miniature mass spectrometer has the potential to meet the government requirements of 10-ppb sensitivity for hydrazine detection, as well as the requirements for instant response, portability, and low maintenance. The sensitivity of the instrument was increased by installing a new ionizer and by increasing the voltage from 600 to 1450 V.

In ion mobility spectrometers, a small portion of an air sample that is drawn over the surface of a semi-permeable membrane and transferred to the detector side of a membrane through solution, diffusion, and evaporation mechanisms. Molecules that pass through the membrane are transferred to an ionization region and mixed with a secondary sample of air containing a dopant. A radioactive source generates high-energy particles that cause the formation of positively and negatively charged ion clusters. These ions are eventually separated, collected, and quantified using TOF differences like those in a TOF mass spectrometer.

Ion mobility spectrometry (IMS) has the advantage that it does not require a hard vacuum like conventional mass spectrometers but can operate at atmospheric pressure. IMS separates ions by time differences it takes them to drift through a gas at atmospheric pressure in an applied electrostatic field. The drift tube is the central part of the instrument. At the inlet to the drift tube is an ionizer, most commonly a  $^{63}\text{Ni}$  radioactive foil like the one used in some household fire alarms/smoke detectors. In the air sample, the  $\beta$  particles ionize compounds with high proton affinity such as hydrazines to become positive ions, whereas other compounds such as halocarbons with high electron affinity form negative ions. Ammonia, hydrazine, and MMH have characteristic drift times and arrive at the collector electrode at the downstream end of the drift tube at different times. With response times from 0.1 to 1 s, reported sensitivities for other toxic contaminants from 0.1 to 10 ppb, simplicity of operation, and the potentially compact size of the instruments, this method has been subjected to intense investigation as a method for the detection of hydrazine and MMH. Early evaluation was done with laboratory-built one-of-a-kind instruments, and later testing was conducted with commercially available units. In early laboratory testing, it was demonstrated that the limits of detection for hydrazine and MMH were near  $0.01\text{ mg/m}^3$  and that the response was linear between 0 and  $0.05\text{ mg/m}^3$  but became flat above  $0.1\text{ mg/m}^3$  [1122]. A modified hand-held ion mobility spectrometer manufactured by Graseby Ionics has been evaluated as a field analyzer for  $\text{N}_2\text{H}_4$  and MMH. During initial testing, the minimum detection level for MMH was found to be 6 ppb with a 0 to 1 ppm total analytical range and an insensitivity to humidity. The initial observed ammonia interference was decreased by changing the internal dopant to 5-nonanone from acetone [1123].

Hydrazine, MMH, and UDMH in air can be detected and identified by IMS at low concentrations, but with interference from ammonia [1124]. The optimum spectrometer operating conditions for the detection of hydrazine, MMH, and UDMH in the presence of ammonia were incorporated into a hand-held portable instrument capable of near real-time detection. Ammonia is still an interferent in the IMS detection of the parent hydrazine. The use of ketones as dopant chemicals has been shown to be effective in the ion mobility spectrometric determination of hydrazines.

An ion mobility spectrometer was flown on two Space Shuttle missions: STS-37 and STS-49 [1125–1128]. The external side of the space suit of astronauts returning from EVA work was sniffed in the airlock before the astronauts were allowed to return to the crew cabin. No hydrazines were detected.

### 3.6.15.8 Thin-Film Electric Conductometric Detectors

Chemiresistors change their electric conductivity in the presence of certain chemicals. The Spire Corp. and Spectral Sciences Inc. initially developed a conductive polymer-based dosimeter using poly(3-hexyl) thiophene-based sensing elements [1129].

Thin films of the electrically conducting polymer, poly(3-hexylthiophene) (P3HT), were developed as sensors for hydrazine vapor at the part-per-billion level [1130–1132]. The P3HT films were fabricated by a spin-coating technique onto quartz substrates incorporating gold-interdigitated electrodes and were rendered conductive by doping with an NOPF<sub>6</sub> solution. The sensors responded strongly and instantaneously to hydrazine concentrations as low as 1 ppb with a measurement accuracy of  $\pm 20\%$ . In addition, the sensors exhibited excellent environmental stability and a long shelf life and were free from interference by contaminants.

The original sensor demonstrated a minimum detectable dose of approximately 1 ppb  $\times$  h and a saturation dose of approximately 250 ppb  $\times$  h as measured in dry conditions. In a humidified environment with greater than 60% RH, the output of the sensor changes significantly [1133].

Two thin-film electronic noses, the Cyranose (a commercial product) electronic nose and an electronic nose developed at JPL, both consisting of an array of 32 sensors made of polymer-carbon composite films, were tested to determine their utility for detecting hydrazine and MMH [1134]. The devices were exposed to concentrations of hydrazine from 0.5 to 52 ppm, and 14 ppm and 1 ppm MMH. The Cyranose sensors responded to hydrazine at 52 and 18 ppm; the JPL developmental ENose sensors responded to hydrazine at 3 ppm. The response of the Cyranose to 1.1 ppm hydrazine was not measurable; the response of the JPL ENose sensors to 0.5 ppm was evident but was obscured by a humidity change. The Cyranose sensors responded to 14 ppm and 1.1 ppm MMH.

A poly(3-hexylthiophene) conducting polymer-based thin-film microsensor for a real-time detection of hydrazine vapor at ambient pressure consisted of a rectangular shaped inert substrate and gold electrode pairs [1135]. A layer of poly(3-hexylthiophene) thin film was coated onto the sensor platform using a spin-coating method, and nitrosonium hexafluorophosphate (NOPF<sub>6</sub>) was used to dope the poly(3-hexylthiophene) thin film to increase its electrical conductivity and form the finished sensor. The results showed that the sensor responded to hydrazine vapor in less than a few seconds, attained orders of magnitude change in normalized resistance during hydrazine exposure, and was not easily saturated. When exposed to 1 ppm of hydrazine vapor, the compensation interaction between the reducing hydrazine gas and p-type doped poly(3-hexylthiophene) leads to a five-order-of-magnitude increase in the resistance of the device [1136]. The sensor can detect hydrazine in concentrations from tens of ppb to tens of ppm. The sensitivity of the sensor increased with increasing hydrazine concentration and decreasing polymer film thickness.

A review article covered the main applications of conducting polymers in chemiresistor sensors for sensing hypergolic liquid propellant vapors and toxic exhaust plume acidic vapors of solid rocket motors at TLV concentration levels [1137]. This included NO<sub>2</sub> and mixed oxides of nitrogen (MON-3), hydrazine, MMH, UDMH, and HCl. Discussion of key features of the sensors such as conducting mechanisms during sensing, thickness of the sensing layer, factors that influence conductivity, response time, recovery time, detectable range, and minimum detectable limit constitutes a good introduction to this topic.

Thin films containing bis(diethylaminodithiobenzil) nickel films and stearyl alcohol in a 1:1 molar ratio are electrically conductive. Chemiresistor sensors were fabricated by depositing thin layers onto interdigital electrodes [1138, 1139]. The current passing through these sensors increased by three orders of magnitude on exposure to parts-per-billion levels of hydrazine, with high signal-to-noise ratios. Exposure to potential interferents such as ammonia at 29 ppm or 60% RH at room temperature caused current increases of only 10- to 20-fold. These sensors hold promise for use in alarm devices for hydrazine.

#### 3.6.15.9 Differential Temperature Detectors

A hydrazine vapor detector has been proposed that consists of an alumina pellet with 28–36% iridium, similar to Shell 405 catalyst [1140]. When N<sub>2</sub>H<sub>4</sub>, MMH, or UDMH vapor comes into contact with the catalyzed pellet, the temperature change resulting from hydrazine decomposition and oxidation is sensed by a thermistor and compared to that of a non-promoted reference alumina pellet in a Wheatstone bridge type circuit. This type of sensor would respond to hydrogen and numerous other flammable vapors as well.

Electrochemical hydrazine detectors typically saturate at levels above 500 ppm and cannot be used for the detection of flammable levels of UDMH or MMH vapors. Instead, a Bacharach Model 301 Portable Combustible Gas Detector was modified for the detection of flammable levels of hydrazine fuels, mostly UDMH and MMH [1141]. The vapor/air sample is drawn through a cell with two heated platinum thermistor elements in a Wheatstone bridge circuit, like thermal conductivity detectors in gas chromatographs. One thermistor is coated with an inert material to prevent its reaction with combustible vapor, the other is in contact with the vapor/air stream, allowing catalytic combustion to take place on its surface and thus upsetting the balance of the Wheatstone bridge. Since the instrument was designed for methane detection, which oxidizes only at higher temperatures than UDMH, the current to the thermistors and their surface temperature had to be reduced.

A hydrazine leak sensor was developed based on chemically reactive thermistor beads [1142]. The sensor consisted of a thermistor bead coated with copper(II) oxide (CuO) dispersed in a clay or alumina binder. The CuO-coated thermistor was one of a pair of closely located thermistors, the other being a reference. On exposure to hydrazine the CuO reacted exothermically with the hydrazine and increased the temper-

ature of the coated thermistor by several degrees. The temperature rise was sensed by a resistive bridge circuit and an alarm triggered by data acquisition software.

### 3.6.15.10 Optical Direct IR Absorption Methods for Detection of Vapors

The MIRAN SapphiRe, manufactured by the Foxboro Corporation, is a portable ambient air analyzer capable of analyzing for over 100 individual chemicals [1079, 1080]. Using an optical filter and a variable pathlength gas cell (0.5 to 1.5 m), the SapphiRe can measure both parts-per-billion and parts-per-million concentrations of chemical vapors. In the case of  $\text{N}_2\text{H}_4$ , the measurement range is 0 to 50 ppm, with a detection limit of approximately 500 ppb. A SAPPHIRE Portable Gas Detector is also offered by Enmet.

### Open-Path IR Absorption Methods, also with Lasers as Light Source

A lead-salt tunable diode laser cooled to 85 K and operating near  $962\text{--}966\text{ cm}^{-1}$  was used to record direct absorption and second-derivative spectra of hydrazine at several pressures to study the sensitivity to low levels of hydrazine [1143]. Spectra of  $\text{NH}_3$  and  $\text{CO}_2$  were used for wavelength identification of the scanned region. Measurements were made in a 50-cm quartz cell with multiple reflections. With a cumulative pathlength of 80 m, detection sensitivities of about 1 ppb were achieved for hydrazine in dry nitrogen at a cell pressure of 10 mbar. For spectroscopic detection of  $\text{N}_2\text{H}_4$  using the  $10.6\text{-}\mu\text{m}$  band, spectral regions including strong  $\text{NH}_3$  lines or  $\text{CO}_2$  lines must be avoided. Ammonia was always present when the hydrazine concentration was measured. The ammonia signal was at least an order of magnitude stronger than the hydrazine signal. This particular laser diode could only cover narrow regions near 962 and  $965\text{ cm}^{-1}$ , where strong ammonia interferences were expected. However, the high resolution ( $0.001\text{ cm}^{-1}$ ) of the TDL spectrometer allowed individual lines of hydrazine to be identified far from interferences from either ammonia or carbon dioxide, especially at lower pressures. A hydrazine line at  $961.75\text{ cm}^{-1}$  was identified that was free from ammonia absorption interference and that would be suitable to monitor hydrazine levels.

### Laser Photoacoustic Spectroscopy

In photoacoustic spectroscopy, the gas to be analyzed is irradiated by intermittent light of a preselected wavelength coincidental with an absorption band of the analyte, such that the gas will absorb part of the light and warm up. The heat generated by the absorbed light causes the gas to expand and results in a local pressure rise. By chopping the light, the pressure alternately increases and decreases and generates an acoustical signal. This signal is subsequently detected by a microphone and amplified.

### 3.6.15.11 Optical-Emission Chemiluminescence Detectors and Monitors

Chemiluminescence reactions can occur in the gas, liquid, and solid phases. The light emitted from chemiluminescent reactions has differing degrees of intensity, lifetime, and wavelength. The wavelength can extend across the entire spectrum from near UV through the visible and into the near IR. Solution phase chemiluminescent reactions that have found analytical application often produce light in the visible region.

Tris (2,2'-bipyridine) ruthenium (III) ( $\text{Ru}(\text{bpy})_3^{3+}$ ) is an electrogenerable, chemiluminescent reagent that is electrochemically reversible and is a reagent for the detection of gas-phase hydrazine, MMH, and UDMH [1144, 1145]. The electrochemical oxidation of  $\text{Ru}(\text{bpy})_3^{2+}$  to  $\text{Ru}(\text{bpy})_3^{3+}$  creates a strong oxidizer, whose reduction back down to  $\text{Ru}(\text{bpy})_3^{2+}$  by reaction with a reducing analyte is characterized by the emission of photons of light centered at 610 nm. Portable and semi-portable instruments that rely on the chemiluminescent reactivity and reversibility of the  $\text{Ru}(\text{bpy})_3^{3+}$  reagent have been designed and tested. Detection limits for hydrazine and its derivatives were in the low-ppb regime, while response times were on the order of seconds to several minutes, depending upon the analyte being examined.

A chemiluminescence analysis method for hydrazine combined with flow-injection technique used luminol and hexacyanoferrate(III), both of which were immobilized on an anion-exchange column [1146, 1147]. The chemiluminescence signal produced by the reaction between luminol and hexacyanoferrate(III), which were eluted from the column through sodium phosphate injection, was decreased in the presence of hydrazine. The decrease in chemiluminescence intensity was linear with hydrazine concentration in a range from 0.1 to 100 ng/mL, and the detection limit was 0.04 ng/mL ( $3\sigma$ ).

### 3.6.15.12 Electrochemical Potentiometric Detectors and Monitors

In hydrazine electrochemical sensors, the measured current is generated by the oxidation of  $\text{N}_2\text{H}_4$ , MMH, or UDMH in an electrolytic cell. The output current of the detector is directly proportional to the concentration of the hydrazine vapors that pass by a sensing electrode. The specificity of the electrochemical system can be improved by properly selecting the sensing electrode, supporting electrolyte, and the potential difference between the reference and sensing electrodes. Some electrochemical systems employ a third electrode, or counterelectrode, to provide added stability.

The Interscan series 4000 series 2-electrode electrochemical monitor was supposed to be capable of detecting  $\text{N}_2\text{H}_4$  and MMH vapor concentrations at the 10-ppb level. This analyzer has somewhat high maintenance needs since it requires the periodic addition of water to the electrochemical cell [1080, 1148]. The depletion of the water from the cell is due to the evaporation of supporting electrolyte as sample air is pumped across the surface of the sensing electrode. The overall life of the cell is decreased due to the intrusion of atmospheric  $\text{CO}_2$  into the cell and the subsequent formation of carbonates. Although the formation of carbonates cannot be stopped, the substitution of cesium hydroxide ( $\text{CsOH}$ ) for potassium hydroxide ( $\text{KOH}$ ) has led

to a more soluble carbonate species and helped to prevent plugging of the sensor membrane. However, the Interscan 4187 often did not read zero when clean air was passed through the instrument, and NASA KSC is phasing out the use of the Interscan 4187 instrument.

NASA has developed an area vapor monitor that has the capability to continuously monitor and detect hydrazine vapor concentrations in the workplace that might be present at both the proposed 10 ppb TLV level, as well as at leak levels as high as 10 ppm. Commercially available boiler feedwater analyzers with platinum/stainless-steel electrodes have been adapted to analyze hydrazine vapor concentrations in air [831, 1149, 1150]. A prototype area monitor analyzer system based on the MDA/Hach Polymetron 9186 or 9586 Hydrazine Analyzer capable of meeting these requirements and operating unattended for 90 d (24 h/d) on a continuous basis was demonstrated. This analyzer is a three-electrode liquid analyzer typically used in boiler feedwater applications. For air monitoring, the system incorporated a dual-phase sample collection/transport method that simultaneously pulled ambient air samples containing hydrazine and a very dilute sulfuric acid solution (0.0001M) down a length of 1/4 in.-outer-diameter tubing from a remote sampling site to the analyzer. The hydrazine-laden dilute acid stream is separated from the air, and the pH is adjusted by the addition of a dilute caustic solution to a pH greater than 10.2 prior to analysis. See also [1151].

## 4 Decomposition of Hydrazine

In most of this book's chapters, the decomposition of any given rocket propellant is discussed as part of the chemical properties of a given substance. In deviating from this format, in the current chapter the decomposition of hydrazine has been moved to a section of its own, not as a subsection of chemical properties, because it is such an important property of hydrazine and has generated a flood of publications. There are many different modes of initiating the decomposition of hydrazine, including thermal, photolysis, radiolysis, and catalytic decomposition.

This section on hydrazine decomposition and combustion comprises a relatively large fraction of the total volume of this chapter because so many industrial applications depend on controlled hydrazine decomposition on command. Also, safety hazards can be caused by unexpected, accidental, and catastrophic hydrazine decomposition events that need to be prevented by a better understanding of decomposition mechanisms and triggers. Therefore, a better understanding of handling safety can be obtained and possibly new applications identified if all decomposition properties of hydrazine and its mixtures and derivatives are known and thoroughly understood. This includes decomposition in the absence of catalysts and controlled decomposition with the aid of catalysts. Only if the decomposition of hydrazine is completely understood from all points of view (i.e., academic and engineering points of view) will it be

possible to develop methods for the controlled decomposition of hydrazine and acquire a better understanding of conditions to avoid being a casualty of unexpected hydrazine explosions. Because the decomposition of hydrazine is important for most of its industrial uses, the fundamentals of decomposition kinetics are covered in this chapter, which includes such topics as kinetic rates, activation energy, free radicals, and isotope labeling.

Ever since the discovery of hydrazine (and hydrazine hydrate), its decomposition has undergone a very thorough investigation. This has resulted in a flood of publications beyond those modest eight initial works referenced in Audrieth's first monograph on hydrazine several decades ago [7]. It is difficult to organize all this material in a systematic, user-friendly fashion. The experimental methods for studying hydrazine decomposition differ as widely as the results, and it is not always easy to draw final conclusions when the data obtained by different methods agree with or contradict each other. In this chapter, the material was arranged by the mode of decomposition. Information on the decomposition of hydrazine derivatives, such as methylhydrazines, will be discussed in *Encyclopedia of Liquid Fuels* in the chapter "Methylhydrazine." The decomposition of hydrazinium salts was already presented in a separate section on the thermal stability of hydrazinium salts in *Encyclopedia of Oxidizers*, chapter "Hydrazinium Salt Oxidizers." Applications of hydrazine as a monopropellant that depend on controlled decomposition will be discussed in *Encyclopedia of Monopropellants*, in the chapter on monopropellants.

Most academic investigators have studied the vapor-phase decomposition of pure or diluted hydrazine at low partial pressures in glass or quartz apparatus. This may be useful for kinetic studies, but it does not reflect the actual operating pressure of hydrazine decomposition reactors for industrial applications. A significant fraction of hydrazine in a modern design rocket engine reactor decomposes catalytically, and only a small fraction decomposes thermally. Relatively few papers have examined the mechanism of hydrazine decomposition on the surface of heterogeneous catalysts because at higher temperatures, so many different mechanisms take place in parallel and simultaneously.

Throughout the various efforts to study the kinetics of hydrazine decomposition, the use of isotope-labeled hydrazine has proved very useful. The isotope-labeled hydrazines are not useful as rocket propellants. However, we regard them only as a means to obtain kinetics results and shall review them at the appropriate section depending on the mode of decomposition. Nitrogen-15-isotope-labeled hydrazine has been used in photolysis [1152, 1153], thermal decomposition, and oxidation [518] studies of hydrazine. The use of  $^{15}\text{N}$  isotope marking is very convenient because the isotope is not radioactive and does not require special safety precautions. Nitrogen-15-labeled hydrazine has also been used for studying the quadrupole moment and molecular structure of hydrazine. Other than replacing nitrogen atoms at the backbone of the molecule, isotope labeling of hydrazine could also be accomplished by the replacement of hydrogen with deuterium. This method has

been widely used in IR and Raman spectroscopic studies of the hydrazine molecule. The decomposition rate of  $N_2D_4$  has been shown to be markedly different from that of  $N_2H_4$  as a result of the isotope effect [1154]. The use of  $\bullet OD$  radicals instead of  $\bullet OH$  radicals has facilitated identification of intermediate products of the hydrazine oxidation flame [560].

Throughout the discussion of the kinetics and thermodynamics of hydrazine decomposition it is very important to know the bond dissociation energies (Section 2.3.3), because unless sufficient energy is pumped into the system to break at least one of the bonds, no decomposition may occur, at least not thermodynamically. Molecules are reluctant to dissociate if they have the same bond energy as carbon in diamond. The activation energy is a barrier to decomposition. In order for hydrazine to decompose on command, the most frequently used method is the lowering of the activation energy. The lowering of the activation energy by catalysis is discussed in Section 4.12.

#### 4.1 Slow and Accelerated Liquid-Phase Decomposition During Storage

The main interest in the slow liquid-phase decomposition of hydrazine stems from practical concern about unwanted pressure buildup during storage and the effect of various materials of construction on the rate of such pressure buildup. Some of the concern has carried over from the previous historical use of hydrogen peroxide as a monopropellant, where liquid-phase decomposition and pressure buildup during storage was and remains a serious design limitation. It has been proved that hydrazine can be stored for several decades without excessive pressure buildup or loss of performance. For instance, VOYAGERS 1 and 2 are still operational after 46 years in space.

The current section deals only with the slow decomposition of liquid hydrazine(s) during storage. Liquid-phase decomposition during conditions other than room-temperature storage is discussed in Section 4.2. Liquid-phase decomposition under catastrophic conditions (bonfire test) will be discussed in Section 8.12.

Experimental techniques used to study the effect of materials of construction, contaminants, or stabilizers on the decomposition of liquid hydrazine during storage include gas evolution/pressure buildup, differential thermal calorimetry, microcalorimetry, and chemical analysis of hydrazine(s) before and after long-term storage.

##### 4.1.1 Effect of Container Materials

A more detailed summary of suitable materials of construction is given in Section 5.3. The current discussion centers only on materials for laboratory experiments in which the slow decomposition of pure hydrazine is studied, preferably without any interference from the wall material. Since the liquid must somehow be contained under

terrestrial conditions to keep it from flowing away, container wall effects are difficult to avoid. For laboratory tests, the least interference is generally encountered with the use of borosilicate (e.g., Pyrex) glass or quartz.

The kinetic rate data of homogeneous hydrazine decomposition obtained by different authors and using different methods were combined on an Arrhenius plot, and fortunately all fell on the same straight line [1155]. The kinetics of the homogeneous decomposition of hydrazine did not change over a wide temperature range (~240 °C) and an extremely wide range of the rate constant (approximately nine orders of magnitude). The expression for the rate constant is

$$k = 5 \times 10^{6.0 \pm 0.2} \exp\left(\frac{-26800 \pm 800}{RT}\right)$$

where  $k$  is the rate constant in  $\text{s}^{-1}$  and  $T$  is the temperature in kelvin. These tests were repeated for the heterogeneous decomposition of hydrazine in contact with various materials of construction. The kinetic constants for these conditions are summarized in Table 48.

**Table 48:** Kinetic rate constants for heterogeneous decomposition of hydrazine on surface of materials of construction.

| Material                   | Temperature |        | Pre-exponential factor | Activation energy |
|----------------------------|-------------|--------|------------------------|-------------------|
|                            | K           | °C     | $\text{cm s}^{-1}$     | kJ/mol            |
| Stainless steel H18N10T    | 303–533     | 30–260 | 13                     | 66.7              |
| Stainless steel 12H18N10T  | 313–403     | 40–130 | 380                    | 76.7              |
| Nickel-based alloy El654   | 313–403     | 40–130 | 15                     | 72.9              |
| Stainless steel 12H21N51   | 313–403     | 40–130 | 29                     | 72.1              |
| Teflon film                | 323–368     | 50–95  | 25                     | 82.9              |
| Aluminum-based alloy AMG-6 | 323–403     | 50–130 | 12                     | 90.8              |

Data source: [1155]

The inseparable interaction of liquid-phase and vapor-phase thermal decomposition of hydrazine is evident [1156]. Borosilicate glass tubes 3 to 7 mm in diameter were used in this study. A weighed amount of liquid hydrazine was inserted above a plug of mercury, taking care to prevent gas bubbles. The movement of the mercury column as a function of time, temperature, additives, and pressure was then measured. Since the initial ullage was zero, the initial vapor space must result from the decomposition of pure liquid hydrazine. After the vapor space was produced, decomposition could occur in either phase. The data did not reveal whether either of the two decomposition modes was heterogeneous. After a constant initiation period, the decomposition rate remained constant, whereas the surface area to which vapor was exposed changed continuously. The rate of decomposition was independent of the tube diameter. The

tubes could be placed in a pressurized chamber environment to compensate for the vapor pressure of hydrazine. The rate of decomposition increased from  $10^{-4}$  to 1%/h over a temperature range of 448–523 K. An activation energy of 304.2 kJ/mol (72.7 kcal/mol) was obtained from an Arrhenius plot of the data. However, this value is significantly higher than the activation energy obtained for hydrazine in the vapor phase by numerous other investigators (Section 4.3). The discrepancy is most likely due to different mechanisms of decomposition in the liquid and vapor phases. The generation of a small gas bubble under Lucien's conditions acted quasi-autocatalytically, in that decomposition in the vapor phase occurs more rapidly than in the liquid phase at identical temperatures. This is illustrated by the pressure effect on hydrazine decomposition: at 495 K, a change in pressure from 2.06 MPa (300 psi) to 2.96 MPa (430 psi) reduced the rate of decomposition from 1.8 to 0.04%/h. The higher pressure delayed the formation of a bubble by keeping the decomposition gases dissolved for a longer period of time until the liquid was saturated. Ammonia addition had a distinct retarding effect on hydrazine decomposition: at 495 K and 2.06 MPa, the rate decreased from 1.8 to 0.4%/h when 2.5% ammonia was added. The nitrogen : hydrogen ratio was dependent on reaction time, pressure, or ammonia concentration and was inversely proportional to all these variables.

Regarding the stoichiometry of the liquid-phase decomposition, the decomposition proceeds mainly through

Only small amounts of hydrogen are observed as a result of

It was concluded that hydrazine is “relatively stable” under the conditions described [1156]. One question was not discussed in that paper – the possibility of interaction between hydrazine and the mercury used to seal the sample. Hydrazine decomposition is catalyzed by many metals, and a catalytic contribution of mercury (or its contaminants) to the observed results cannot be excluded. The activation energy derived from an Arrhenius plot of gas evolution rate measurements between 343, 353, and 363 K was 66.3 kJ/mol in glass, 61.1 kJ/mol in aluminum, and 50.6 kJ/mol in CRES-304 [1157, 1158]. It is a misrepresentation of physical and hazard properties of hydrazine to state that “... the liquid (hydrazine) is relatively stable at temperatures to 300 °C” [1159]. The source quoted for this statement [9] originally said, “Anhydrous hydrazine decomposes on heating in the absence of oxygen at a temperature above 300 °C.” This does not preclude that unexpected, unwanted, but potentially catastrophic decomposition may occur far below 300 °C. The upper temperature limit of storability depends to a large extent on the materials of construction, the size of the container, and the surface : volume ratio. For the hazards caused by the lack of thermal stability, see Section 8.12.

On the basis of 10-year storage tests in an all-glass apparatus, the rate of decomposition of hydrazine at 316 K (110 °F) is 0.015%/year in the absence of metal surfaces and catalytic contaminants [1160–1162]. The rate of decomposition was identical for MIL-SPEC monopropellant-grade and high-purity-grade (“VIKING-grade”) hydrazine. In the presence of the most inert metal specimens (Ti-6Al-4V), the rate of decomposition increased to 0.15%/year. In the same test, MMH decomposition was only 0.02–0.1%/year.

The gas evolution rate of hydrazine in a glass isoteniscope at 294–305 K was slightly above  $3.67 \times 10^{-15} \text{ m}^3 \text{ g}^{-1} \text{ s}^{-1}$  [1163]. The gassing rates of MMH and UDMH were of the same order of magnitude. When plotting the logarithm of the gas evolution rate of hydrazine against reciprocal temperature, the slope of the curve changed abruptly at 300 K, showing steeper slopes at higher temperatures.

The sealed vial storage stability tests by Rocketdyne [1164–1170] were later repeated (with smaller surface : volume ratios) at Stanford Research Institute (SRI), also in comparison to the decomposition of MMH [1171]. Although the Rocketdyne tests showed that added glass surface had little or no accelerating effect on the decomposition of propellant-grade hydrazine, the SRI apparatus with only 6% of the surface area also had only 10% of the rate of decomposition. At 448 K, 2.55% of the hydrazine was decomposed after 572 h. The decomposition products consisted of 78.8% ammonia, 17.8% nitrogen, and 3.4% hydrogen. The average rate of decomposition was 0.0045%/h.

Hydrazine decomposition reactions in dilute aqueous, oxygen-free solutions at very high, supercritical pressures in water, up to 703 K (430 °C) and 35.5 MPa (350 atm), were studied by Raman spectroscopy in a high-pressure optical cell with diamond windows [1172]. The decomposition reaction appeared to be a first-order reaction. The effective first-order rate constant at 673 K was  $0.32 \text{ s}^{-1}$ . This study is of interest for the application of hydrazine solutions as boiler feedwater additive.

Many satellites have electric heaters wrapped around or traced alongside hydrazine propellant lines to prevent freezing while the spacecraft is pointing away from the Sun or while it is in the shadow of the planet or moon around which it revolves. One of the possible failure modes involves a stuck thermostat relay and accidental overheating of the lines. Line heater simulation tests have heated hydrazine in CRES-321 line sections to as high as 538 K (510 °F) without explosion [1173]. Laboratory tests simulated the situation where both primary and redundant heater thermostats failed in the closed (energized) position. Thermal analysis predicted that this situation could result in heating the propellant to 538 K (510 °F). To simulate this condition, in a first series of tests, 27.9 cm (11 in.) of propellant line upstream of a valve were traced with strip heaters, instrumented, and insulated. After initial tests at 422, 450, and 477 K (300, 350, 400 °F) were uneventful, the experimenters were more “gutsy,” and tests at 505 and 538 K (450 and 510 °F) were added to the test matrix. The hot section of the line slowly filled with gaseous decomposition products and the liquid/vapor front receded to cooler zones. Thruster firing tests were conducted

at 422, 450, 477, 505, and 538 K (300, 350, 400, 450, and 510 °F). The propellant was held in the heated tubing for 24 h prior to the firing. Other than reduced thrust due to gas bubble ingestion, the thrusters worked normally, and no explosions occurred on shutdown. The valve was solidly thermally shunted to the mounting plate, such that the valve never heated to the temperature of the first slug of incoming propellant. Subsequent fresh propellant cooled both the lines and the valve. In a second test series, stagnant propellant in a 53-cm (21-in.) line was heated such that two-thirds of the line were at temperature for up to 4 weeks and the ullage pressure was monitored. These tests did not produce any explosions either.

Previously, to obtain measurable thermal effects with conventional DTA, DSC, or ARC equipment, the samples had to be heated to at least 373 K. With the advent of more sensitive microcalorimetry, the rate of decomposition of hydrazine could be measured at room temperature for the first time [1174]. Microcalorimetry has been used to determine battery life, exothermic corrosion, or storage stability of rocket propellants. Microcalorimetry is approximately 10000 times more sensitive than other techniques (DTA, DSC, ARC). Microcalorimetry instruments measure heat flow in a range from 298 to 328 K. Some instruments can measure heat flows as low as  $0.5 \mu\text{J/s}$ , which corresponds to a hydrazine decomposition rate of  $4 \times 10^{-12} \text{ mol/s}$  (4 picomol/s). The samples (3 mL hydrazine and metals under investigation) were typically loaded into a 9-mL titanium bulb. The bulbs were identical to those used in ARC studies and can resist internal pressure of up to 9 MPa. Steady-state heat flux measurements were made at three temperatures, 298, 313, and 328 K. When converting heat flow data to rate of hydrazine decomposition, the theoretical heat of reaction had to be corrected for the heat of solution of ammonia in hydrazine. The metals under study were added as powders, and the surface area of each sample was measured beforehand. In this way, the reaction rate could be normalized by the wetted surface area to eliminate variations due to different particle size. The steady-state heat evolution rates were sorted by increasing catalytic activity at 328 K, as summarized in Table 49. The catalytically most active metals were molybdenum and nickel.

**Table 49:** Heat evolution and kinetic rate data of metal powders in liquid hydrazine.

| Metal powder | Heat evolution, $\mu\text{J s}^{-1} \text{ m}^{-2}$ |          |          | Frequency factor <i>A</i>           | Activation energy |
|--------------|-----------------------------------------------------|----------|----------|-------------------------------------|-------------------|
|              | at 298 K                                            | at 313 K | at 328 K | $\mu\text{J s}^{-1} \text{ m}^{-2}$ | kJ/mol            |

Data source: [1174]

An attempt was made to correlate hydrazine decomposition data obtained from different thermal stability measurement methods (NASA NHB8060.1C Test 15, ARC and microcalorimeter) since they are all the result of the same hydrazine decomposition mechanism (Table 50). One such attempt to correlate thermal stability/exothermicity measurements led to the development of a computer program called HYKIN [1175], which is useful for data reduction and data correlation from all three methods and for making predictions for real-life situations outside the temperature range tested in the laboratory. The data were converted to a common denominator unit as  $\text{mol s}^{-1} \text{m}^{-2}$  (or  $\text{picomol} = \text{pmol cm}^{-2} \text{s}^{-1}$ ) and then compared. When plotted in an Arrhenius plot, data from the three methods for molybdenum showed good agreement. Less satisfactory agreement was found when plotting the Hastelloy-C data, which differed by a factor of 2 to 3, but at least they were of the same order of magnitude.

**Table 50:** Liquid hydrazine decomposition rates measured by different methods.

Data source: [1174]

The acceleration of thermal decomposition of hydrazine caused by metals was measured using a differential scanning calorimeter and SuperCRC [1176]. The DSC measurements revealed that the exothermic reactions of  $\text{N}_2\text{H}_4$  depended on the type of sample cells. The onset temperature in a differential scanning calorimeter with a gold pan was 485.2 K and that with a glass capillary was 620.5 K. The activation energy of the thermal decomposition of  $\text{N}_2\text{H}_4$ , calculated from the Kissinger and Ozawa methods, were  $38 \pm 2 \text{ kJ/mol}$  in the gold pan and  $141 \pm 8 \text{ kJ/mol}$  in the glass capillary. A heat flow profile was observed with SuperCRC during the mixing of  $\text{N}_2\text{H}_4$  and a metal ion solution at 298 K. The maximum heat flow was related to the metal ion oxidative characters. The higher oxidative characters would provide a faster acceleration for the exothermic behavior than the lower oxidative ions. Mn(VII) and Cr(VI) solutions exhibited strongly oxidative characteristics during mixing with  $\text{N}_2\text{H}_4$ .

#### 4.1.2 Hydrazine Hydrate Slow Liquid-Phase Decomposition

The decomposition of hydrazine hydrate during storage in sealed vials was measured [541]. As long as air was excluded, the concentration of the 100% hydrazine

hydrate (64% hydrazine) did not change when stored in Pyrex containers at up to 343 K, even in the presence of 10% sodium hydroxide or potassium hydroxide. However, if the glass stopper was allowed to leak in air, hydrazine concentrations dropped from 64% to 42% in 155 d at room temperature. It is important to clean glass vessels before long-term tests with hydrazine. Pre-test cleaning with one of four solutions (10%  $\text{K}_2\text{Cr}_2\text{O}_7$  in  $\text{H}_2\text{SO}_4$ , 50%  $\text{HNO}_3$ /50%  $\text{H}_2\text{SO}_4$ , 42% aqueous KOH, or 3%  $\text{KMnO}_4$ / $\text{H}_2\text{SO}_4$ ) showed that all four solutions worked equally well and did not make any difference as long as the vessels were thoroughly rinsed with distilled water before use with hydrazine hydrate.

#### 4.1.3 Effect of Contaminants and Catalysts

Proton donors appear to destabilize hydrazine. The effect of acidity on the rate of hydrazine decomposition was studied in a simple microcalorimeter at temperatures of 426–474 K with the use of hydrazinium nitrate as an additive [1177]. The reaction velocity is proportional to the concentration of hydrazine *and* its nitrate:

$$\frac{dC_{\text{N}_2\text{H}_4}}{dt} = k_t C_{\text{N}_2\text{H}_4} C_{\text{N}_2\text{H}_5\text{NO}_3}$$

The rate constant is a function of the temperature:

$$k = 10^{12.5 \pm 0.5} e^{\frac{-37000 \pm 1000 \text{ cal}}{RT}} \text{ mol}^{-1} \text{ s}^{-1}$$

Nitrate ions do not influence the kinetics because sodium nitrate addition did not increase the rate of decomposition. The following mechanism was proposed:

No proof has been offered for the existence of any of these intermediates, and the mechanism seems to be quite speculative. The rate constant for the decomposition of pure liquid hydrazinium nitrate where the principal reaction is the catalytic decomposition of hydrazine was previously found to be

$$\frac{dC_{\text{N}_2\text{H}_4}}{dt} = C_{\text{N}_2\text{H}_5\text{NO}_3} \times 10^{12.2} \times \exp\left(\frac{-3800 \text{ cal}}{RT}\right)$$

The increase of the rate of liquid hydrazine decomposition in glass containers with the addition of carbazic acid or ammonium chloride was attributed to the hydrazinium ion formed in either case by protonation of hydrazine. In sealed Pyrex vials, the rate of decomposition of propellant-grade hydrazine acidified with 1% hydrazinium(1+) chloride at 448 K was 40 times higher than that of the control without chloride addition [1171].

Iron(II) carbazate  $\text{N}_2\text{H}_5[\text{Fe}(\text{H}_3\text{N}_2\text{COO})_3]$  is a likely corrosion product when  $\text{CO}_2$ -contaminated hydrazine is stored in steel containers. Addition of the iron(II) carbazate complex  $\text{N}_2\text{H}_5[\text{Fe}(\text{H}_3\text{N}_2\text{COO})_3 \cdot \text{H}_2\text{O}]$  to hydrazine at concentrations equivalent to up to 173 ppm  $\text{CO}_2$  caused an increase in the rate of decomposition in glass vials at 324 K (51 °C) from 0.03 to 0.11  $\text{cm}^3/\text{d}$  [1178–1180]. On adding the iron(II) dicarbazato dihydrazino complex to hydrazine in glassware at 316 K (43 °C), there was no increase in the rate of decomposition of hydrazine. At 316 K (43 °C), addition of the iron carbazate had no measurable effect. The addition of tricarbazatochromium(III) dihydrate to hydrazine in a glass tube at 333 K (60 °C) did not produce an increase in propellant decomposition relative to the undoped hydrazine. Dicarbazatohydrazine nickel(II) was not sufficiently soluble in hydrazine to be included in this test series. Chromium(II) complexes can be oxidized to chromium(III) complexes by hydrazine in anhydrous hydrazine. In solution in anhydrous hydrazine the stable oxidation state of chromium is +3. It has been suggested that the ease with which chromium oscillates between the oxidation states of +2 and +3 in hydrazine is the key to its catalytic activity in the slow decomposition of hydrazine contaminated by chromium ions leached from the walls of stainless-steel drums [1181]. The carbazate salts by themselves are not nearly as active as solutions to which acidic hydrazinium salts have been added [1180]. In tests measuring the rate of gas evolution at 316 and 323 K with and without addition of Mn and Cr carbazate complexes  $[\text{Cr}(\text{H}_3\text{N}_2\text{COO})_3] \cdot 2\text{H}_2\text{O}$ , both individually and together, the addition of acid to hydrazine containing the metal complexes resulted in significant increase of decomposition, higher than either complexes in hydrazine (without acid) or acid in hydrazine (without metals). The mechanism responsible for high rates of gas evolution may be one involving Cr and Mn contaminants in combination with hydrazinium ion. Hydrazinium ion generated from  $\text{CO}_2$  addition to hydrazine in glass vials did not give a linear relationship between carbazic acid content and hydrazine decomposition rate as it was observed in steel containers. The rate of hydrazine decomposition leveled off above approximately 100 ppm  $\text{CO}_2$  equivalent. When  $\text{CO}_2$ -containing hydrazine with a high rate of decomposition that had already spent time in a CRES-304 tank was transferred to a glass bottle at the same temperature, the rate of gas evolution dropped only 20%. This indicated that the majority of the hydrazine decomposition in contaminated, aged hydrazine occurred in the homogeneous phase and only a small fraction of it was catalyzed heterogeneously by the metal surface.

In one study, 100 ppm nickel or cobalt added to purified hydrazine at 303 K in the form of soluble chlorides enhanced decomposition rates to such a degree that the tubes burst from internal overpressure within a week [241]. The pressure rise rate at 9% ullage was 70–100 kPa/week. Iron was a less effective contaminant than nickel or cobalt. Aluminum, titanium, chloride, or sulfate addition caused decomposition rates like the control tubes without contaminant addition.

Hydrazine is indefinitely stable in anhydrous ammonia solution as long as the solution is neutral or acidic, but as soon as sodium amide or sodium metal is added

to create alkaline conditions, hydrazine decomposes rapidly, forming hydrogen and nitrogen gas in a 2:1 molar ratio [1182]. The energy of activation of the uncatalyzed reaction is approximately 54 kJ/mol (13 kcal/mol). Kinetic studies have shown that the liquid-phase decomposition proceeds through an apparent one-half-order reaction. Steel, rust, platinum, or graphite accelerated the decomposition reaction, whereas increasing the Pyrex glass surface : volume ratio had no effect.

#### 4.1.4 Stabilizing Additives

The slow, barely measurable decomposition of hydrazine in contact with common materials of construction may cause a design problem due to pressure buildup during long-term storage. The problem is far less severe with hydrazine than with hydrogen peroxide, which was previously used for space propulsion and continues to decompose at very high rates despite the addition of stabilizers. Following the tradition of hydrogen peroxide problem solving, stabilizers have been sought for hydrazine as well, but none really proved to be effective, nor was one necessary. The search for stabilizers for hydrazine is now a thing of the past. Stabilizers became unnecessary once the propellant handlers understood the importance of impeccable cleanliness requirements for hydrazine systems and once designers stuck to a list of compatible and approved materials for propellant tanks and flow control components.

The rate of propellant-grade hydrazine decomposition can be suppressed by a factor of 0.01 by pre-treatment with barium oxide; however, the same treatment is less effective for MMH. Barium oxide treatment cuts the rate of MMH decomposition only in half [1183].

Ethanol was said to have a stabilizing effect on anhydrous hydrazine, and no loss of hydrazine was measurable after 477 d in a 63 mass-% hydrazine/ethanol mixture [187]. However, the decomposition rates shown for anhydrous hydrazine stored in glass bottles are questionable. More recent data indicate that anhydrous hydrazine can be stored in glass bottles for several years with only minimal decrease in hydrazine and increase in ammonia concentration. In addition to extending the long-term storage duration of hydrazine at room temperature, attempts have also been made to extend the short-term upper temperature limit of safe use of liquid hydrazine to beyond 800 K by addition of stabilizers. These efforts have had only marginal success. The situation is different from that with hydrogen peroxide where several stabilizers are capable of extending the storage life of this notoriously unstable propellant.

Cadmium acetate was said to stabilize liquid hydrazine [1184]. Tests with decomposing hydrazine in a CRES-347 bomb with 60% ullage at 463, 475, 500, and 522 K (375, 395, 440, and 480 °F), 688–12380 kPa (100–1800 psia) for up to 120 min. showed that cadmium plating of the inside wall of the cylinder and addition of cadmium salts to the hydrazine substantially reduced the rate of hydrazine decomposition. In Figure 37, the upper heavy solid line describes the plain steel and the lower light solid line the cadmium-plated cylinder with cadmium acetate added to the liquid.

**Figure 37:** Effect of cadmium plating on hydrazine decomposition rates. (Image created by Schmidt 2020 based on data from [1184])

#### 4.1.5 Decomposition in Aqueous Solutions in the Absence of Oxygen

One of the main applications of hydrazine hydrate solutions is in boiler feedwater deoxygenation. Under these conditions, hydrazine decomposition competes with hydrazine oxidation as an undesirable side reaction. Tests with hydrazine hydrate solutions in dioxygen-free water at high temperatures and pressures have shown that hydrazine hydrate is remarkably stable under these conditions [1185].

In studies with hydrazine hydrate in pure, dioxygen-free water, at least 97% of the initial hydrazine was recovered after 3 h at temperatures between 373 and 573 K at saturation pressures in a passivated CRES-316 reactor [1186]. This means that simple cooking of hydrazine solutions as a means of decontaminating wastewater will not be effective.

The thermal decomposition of hydrazine in sub- and super-critical water at 25 MPa was measured in a super-critical water flow-through test facility [1187]. The thermal stability of hydrazine in aqueous solution was examined along the 25-MPa isobar from 473 to 725 K. The obtained first-order rate constant for the thermal decomposition of hydrazine increased from  $3.73 \times 10^{-4} \text{ s}^{-1}$  at 473 K to about  $0.31 \text{ s}^{-1}$  at 725 K.

## 4.2 Accelerated Liquid-Phase Decomposition

In most cases the rate of decomposition at room temperature is too slow, and the miniscule changes are difficult to measure. To accelerate storage life tests, the samples are stored at two or three elevated temperatures below the thermal runaway temperature, but above room temperature, and the rates of decomposition are plotted against the reciprocal absolute temperature in order to obtain kinetic parameters that will allow us to make predictions about the storage life at lower temperatures. Frequently it is difficult to avoid the effect of container materials on the rate of decomposition. If a totally inert container material cannot be found, the tests must be repeated with different volume:surface ratios so that the surface effect can be zeroed out. Even glass or quartz may have an effect on the rate of decomposition of anhydrous hydrazine.

Occasionally hydrazinium salts are stored as aqueous solutions, in particular if they are shock or friction sensitive, like hydrazinium nitrate, and they cannot be shipped in the solid state. The thermal decomposition of aqueous solutions of hydrazinium salts was already discussed in *Encyclopedia of Oxidizers*, in the chapter "Hydrazinium Salt Oxidizers."

Solutions of hydrazinium nitrate in hydrazine have been tested as monopropellants, liquid gun propellants, and explosives. While these solutions offer higher energy output than monopropellant hydrazine, concern over the lack of thermal stability has prevented their widespread use.

## 4.3 Homogeneous Vapor-Phase Decomposition

Of all various modes of hydrazine decomposition, the homogeneous decomposition of hydrazine vapor is the easiest to study (if one maintains a low pressure in the apparatus). The slow decomposition of liquid hydrazine was already described in Section 4.1. In both cases it is very difficult to study the truly homogeneous reaction without contributions from the reactor walls. The following modes and methods of gaseous hydrazine decomposition have been studied: thermal, hot-wire, photolysis,  $\alpha$ -radiolysis,  $\gamma$ -radiolysis, X-ray radiolysis, shock waves in shock tubes, glow discharges, and catalytic surfaces (thin-film, single-crystal, and polycrystalline surfaces). Test methods may include static tests in a thermostatted chamber with pressure measurement or dynamic tests where vapor flows from a vaporizer or vapor reservoir over a heated (presumably noncatalytic) reactor packing. The dwell time can be varied with the flow velocity.

The various modes of decomposition have several reaction steps in common. To facilitate comparison and discussion of results, a consecutive numbering system for reactions is used throughout this chapter to identify the many possible reaction steps. There is hardly any decomposition reaction of hydrazine(s) that proceeds by a one-step reaction. Many hydrazine decomposition reactions proceed by several pathways in parallel and via short-lived, unstable intermediate products.

A table in [1188] gives a historical survey of the various publications on liquid hydrazine homogeneous decomposition in chronological order. It lists the publications with the operating pressure and temperature range and the method of experimentation used. A schematic of possible reaction steps is shown in Figure 38. The numbers placed next to the arrows will be referenced in the following discussions.

Figure 38: Schematic of hydrazine decomposition reactions

The kinetic parameters for thermal decomposition of hydrazine vapor in oxygen and nitrogen atmospheres were determined by a non-linear isoconversional method [1189]. From thermographic data at heating rates of 5, 10, and 20 °C/min, kinetic parameters could be determined in nitrogen ( $E_{act} = 47.3 \pm 3.1$  kJ/mol,  $\ln A = 14.2 \pm 0.9$ , and  $T_b = 342$  K = 69 °C) and oxygen ( $E_{act} = 64.9 \pm 8.6$  kJ/mol,  $\ln A = 20.7 \pm 3.1$ , and  $T_b = 348$  K = 75 °C) atmospheres. It was not possible to identify a specific kinetic model for hydrazine thermal decomposition due to high heterogeneity in reaction.

#### 4.4 Thermal Decomposition of Hydrazine

The following sections attempt to separate the inevitable effects of wall materials from the kinetics of hydrazine decomposition in the absence of catalysts. Of all the many modes of hydrazine decomposition, the thermal and heterogeneous catalytic decomposition of hydrazine are the two with the most practical importance.

Unfortunately, thermal initiation does not initiate only one specific reaction (as selected wavelength photolysis would do), but a host of competing reactions are ini-

tiated and proceed to varying levels of completion at the same time once the temperature is high enough. Once the critical energy threshold is exceeded, the remainder of the decomposition proceeds in a self-accelerating, avalanche-type fashion. It is difficult to maintain isothermal conditions under these circumstances. The following sections are subdivided by the physical state of hydrazine undergoing the decomposition, hydrazine vapor, hydrazine liquid, and hydrazine solutions.

#### 4.4.1 Thermal Decomposition of Hydrazine Vapor

Most academic thermal decomposition studies (as well as those with other modes of initiation) were conducted with hydrazine vapor. The most dangerous part of these experiments if they are conducted in a flow reactor is the possibility that decomposition may propagate upstream from the reaction zone into the hydrazine vapor reservoir. One will therefore want to minimize the size of the reservoir and use methods where liquid hydrazine is vaporized rapidly without accumulating more vapor than needed to achieve temperature equilibrium before entering the reaction zone. Very little is known about the purely thermal decomposition of the liquid because it only occurs at temperatures where there is already a significant fraction of vapor in the system. A frequent problem is the interaction with the container material, and different results are obtained depending on the type of containment. The current section summarizes decomposition studies with thermal heating (stationary or dynamic flow reactors). Shock-tube studies, essentially also a mode of thermal decomposition but with the heating provided by rapid compression, are summarized in Section 4.4.10.

The use of  $^{15}\text{N}$  isotope-labeled hydrazine has proved very useful in several hydrazine decomposition kinetics studies, including thermal decomposition. In thermal as well as in photolytic decomposition, two different hypotheses have been proposed for the mechanism, and arguments have been advanced to support or disprove each of these possible mechanisms. Even though some of the work referenced in this summary on hydrazine decomposition may already have been superseded by later publications, it is still useful to illustrate the difficulty in obtaining conclusive proof of the decomposition mechanism. With regard to some of the questions, the discussion is still in full swing and the mechanism of hydrazine decomposition is still being actively investigated.

When comparing thermal hydrazine decomposition in a flow reactor to that induced by an alternating current-glow discharge in a flow reactor, the existence of a threshold level of decomposition was a new observation [1190]. The threshold level and experimental data could be explained with a mechanism consisting of three regimes. The first regime is responsible for threshold phenomena, the second regime for the reformation of hydrazine, and the third for the slow decomposition.

Unimolecular rate constants for hydrazine dissociation by thermal and chemical activation have been calculated according to the Rice Ramsperger Kassel Marcus (RRKM) theory [1191]. The two activated complex models used in the calculations rep-

resent plausible upper and lower bounds to the rate constants. The calculations were mainly directed at establishing expected decomposition to stabilization ratios of  $\text{N}_2\text{H}_4$  produced by the (re)combination of  $\text{NH}_2$  radicals; however, a general comparison with available experimental data for hydrazine dissociation was also made.

A useful summary of rate constants reported by various investigators has been compiled as shown in Table 51 [1192]. The results for the rate constant, pre-exponential factors, and activation energies vary widely, depending on the experimental technique used. Note that the gas constant  $R$  has already been combined with the activation energy in the dividend above the line of the quotient that makes up the exponent of  $e$ . Despite the wide scatter of data, several investigators obtained similar activation energies for the overall reaction at high pressures, near 225 kJ/mol.

**Table 51:** Activation energy of hydrazine vapor decomposition.

| Temperature, K           | Rate constant $k$                   | Order       | References |
|--------------------------|-------------------------------------|-------------|------------|
| 935–1085                 | $3.5 \times 10^8 \exp(-15800/T)$    | 1 (or 1/2?) | [1193]     |
| 750–1000                 | $2.2 \times 10^{10} \exp(-18200/T)$ | 1           | [1194]     |
| 1100–1600                | $5 \times 10^{12} \exp(-26170/T)$   | 1           | [1195]     |
| 1100–1600                | $4 \times 10^{15} \exp(-20640/T)$   | 2           | [1196]     |
| $T_{\text{initial}} 333$ | $10^{17} \exp(-17861/T)$            | 2           | [1154]     |
| 1100–1400                | $4 \times 10^{13} \exp(-26700/T)$   | 1           | [1197]     |
| 1100–1650                | $10^{16.25} \exp(-32300/T)$         | 1           | [1198]     |

#### 4.4.2 Free-Radical Mechanisms

One of the questions regarding the decomposition mechanism of hydrazine was whether free radicals are involved. In the following sections, free radicals are indicated by the symbol for the free electron  $\bullet$  added to their formula. Prior to the advent of sophisticated electronic equipment, ortho conversion of para-hydrogen was usually taken as an indication for the presence of free radicals in a reaction. However, no *para-ortho* conversion was detected when hydrazine and parahydrogen were heated to 473 K [1199]. This was initially interpreted as evidence against a radical mechanism [1200]. Szwarc also identified the first step of the hydrazine decomposition to be a dissociation into amino radicals and later proved the presence of amino radicals by reactions with toluene. It is now generally assumed that the thermal and photolytic decomposition of hydrazine involves free radicals.

In a thermal decomposition reaction in the gas phase, the molecules obtain the energy for initiating decomposition by collisional energy transfer. In general terms, a compound AB, such as  $\text{N}_2\text{H}_4$ , does not decompose directly to A and B

Instead, collisions with third bodies M or already excited AB molecules raise AB to an excited state  $AB^*$ , from which it can either deactivate itself by collision with another molecule M or undergo decomposition:

The asterisk \* is used in these equations to identify excited molecules with a statistically significant number of higher states of excitation populated.

The deactivation

and decomposition

reactions compete for the activated  $AB^*$  molecules. The rate of the reaction will be quite different at high pressures, where intermolecular collision is frequent, as opposed to low pressure, where decomposition

is allowed to proceed because the time between collisions is long compared to the half-life time of the excited state. Consequently, one can differentiate between low-pressure and high-pressure mechanisms. The effect of the nature of diluents (third body M) is more pronounced at low pressures than at high pressures. At the high-pressure limit, the effectiveness with which the third body M transfers energy into a collision is of little consequence because statistically there are sufficient collisions taking place to maintain a stationary concentration of  $AB^*$ . However, at low pressure, differences in the effectiveness of  $M^*$  become more pronounced.

The decomposition of hydrazine is presumed to be a chain reaction that, not unlike other chain reactions, can achieve explosive force. All free-radical chain reactions include four fundamental steps: initiation, propagation, branching, and termination. In the case of hydrazine, the first step is the dissociation into  $^{\bullet}NH_2$  radicals (reaction number 1 in Figure 38):

In a study of the bond strength of the N—N bond, hydrazine was decomposed in the presence of toluene in a heated tubular flow reactor presumed to be isothermal [1200]. Toluene served as a radical scavenger for the amino radical by way of

By analyzing the reaction product (dibenzyl) concentration, Szwarc calculated the rate of formation of  $\text{NH}_2$  radicals from  $\text{N}_2\text{H}_4$ :

$$\frac{d[\text{N}_2\text{H}_4]}{dt} = 4 \times 10^{12} e^{\frac{-60000}{RT}} [\text{N}_2\text{H}_4] \quad \text{s}^{-1}$$

Based on this equation, Szwarc [1200] postulated a homogeneous, unimolecular first-order gas reaction. The fraction of hydrazine decomposing to ammonia, nitrogen, and hydrogen was proportional to the surface: volume ratio of the reactor. However, the dibenzyl yield was independent of the surface ratio, which would indicate that the first step is a vapor-phase reaction, whereas consecutive steps leading to hydrazine decomposition depend on the presence of a surface. Szwarc concluded that the reaction does not depend on  $\bullet\text{NH}_2$  free radicals because the presence of a surface would accelerate hydrazine decomposition, but not the rate of  $\text{NH}_2$  radical (and dibenzyl) formation.

In later studies, some doubt was thrown on Szwarc's data by pointing out that the inlet portion of his reactor was not truly isothermal [1201, 1202]. An attempt was made to re-interpret Szwarc's results by assuming that the formation of  $\bullet\text{NH}_2$  radicals is a second-order rather than a first-order reaction. The re-evaluation of the same experimental data gave a rate constant and a reaction order that is, again, consistent with the results obtained from flame data:

$$k = 10^{19} e^{\frac{-60000}{RT}} \quad \text{cm}^3 \text{mol}^{-1} \text{s}^{-1}$$

The experimental results obtained by Szwarc have been discussed and interpreted (or misinterpreted) by numerous investigators, but only one experimental work has become known to check the validity of Szwarc's initial results. The pyrolysis of hydrazine, MMH, and benzylamines was studied by the toluene-carrier technique [1203]. Whereas Szwarc calculated the rate constants for the decomposition of hydrazine from the amount of dibenzyl produced, the exhaust gas composition was now used to calculate the rate constants. The later work discovered that the rate constant  $k_1$  was markedly dependent on toluene pressure, whereas this dependence was previously dismissed as unimportant. The value  $k_1$  is nearly proportional to pressure, whereas Szwarc has postulated independence of the rate on pressure. The pressure dependence of  $k_1$  supports Gilbert's conclusion that the unimolecular reaction forming  $\text{NH}_2$  radicals in the hydrazine flame reaction is in the second-order region. It substanti-

ates his reappraisal of Szwarc's results based on a non-isothermal reactor [1201, 1202], also [1204]. The Arrhenius plot equations by [1205] and [1200] agree closely:

$$\log k_1 = 11.70 - \frac{54150}{2.3RT} \quad (2)$$

$$\log k_1 = 11.39 - \frac{54000}{2.3RT} \quad (3)$$

The following heats of formation have been calculated by equating activation energies with the strengths of bonds broken [1203]:

$$(\Delta H)_f^\circ \quad \bullet\text{NH}_2 \quad 39.8 \text{ kcal/mol} = 166 \text{ kJ/mol}$$

$$(\Delta H)_f^\circ \quad \text{CH}_3\text{NH}\bullet \quad 34.5 \text{ kcal/mol} = 144 \text{ kJ/mol}$$

$$(\Delta H)_f^\circ \quad (\text{CH}_3)_2\text{N}\bullet \quad 29.5 \text{ kcal/mol} = 123 \text{ kJ/mol}$$

This indicated that methyl substitution has a greater weakening effect on N—H and N—N bonds than on the corresponding C—H and C—C bonds.

Because the amino radical plays a key role in the decomposition of hydrazine, its thermochemical and kinetic properties should be thoroughly understood. In another study, it was found that the heat of formation of the amino radical is actually 197 kJ/mol (47.2 kcal/mol), which leads to a dissociation energy  $\text{DH}_0(\text{NH}_2\text{—H})$  of 460 kJ/mol (110 kcal/mol), considerably higher than the value assumed in previous studies [1206].

The decomposition of hydrazine vapor in a quartz tube at 1123 K and 66 Pa and the trapping of decomposition products on a liquid-nitrogen-cooled cold finger moved different distances from the reaction zone resulted in the formation of yellow, short-lived deposits thought to contain hydrazyl radicals and tetrazene [1207]. The yellow material was stable in the solid state at 78 K but decomposed rapidly on thawing. A color change from yellow to white occurred at 95 K. Unfortunately, the investigator overlooked the possibility of forming diazene. Labeling studies with the simultaneous decomposition of  $^{15}\text{N}_2\text{H}_4$  and  $^{14}\text{N}_2\text{H}_4$  showed complete randomization, explained by the presence of hydrazyl radicals.

Hydrazine vapor decomposition tests in an all-quartz isothermal reactor at ambient overall pressure but very low hydrazine partial pressures (achieved by dilution with argon as the inert gas) showed that under these conditions the decomposition is completely heterogeneous over the entire temperature range 542–910 K [1208]. Hydrazine concentrations were on the order of 0.1–4 mM/L, and contact times were on the order of 1 s. The decomposition products consisted mainly of ammonia and nitrogen, with some hydrogen observed only at higher temperatures. Since ammonia itself would not decompose in this apparatus at the highest temperature tested, the source of hydrogen had to be a side reaction of hydrazine decomposition, and not secondary ammonia decomposition. The reactor itself had a surface:volume ratio of  $2.5 \text{ cm}^{-1}$ . When the surface:volume ratio was increased by a factor of 7 to a ratio of  $18 \text{ cm}^{-1}$ ,

the rate of decomposition increased by a factor of up to 23-fold. This indicated that the reaction is very sensitive to surface condition and that the quartz rods inserted to increase the surface may have been of a purity (level of catalytic activity) different from that of the quartz tube from which the reactor was built. The activation energies of the decomposition reactions in the empty and packed reactor were also slightly different. Since this ancient, early (1951) study did not use anhydrous hydrazine, but only a 95.5%  $\text{N}_2\text{H}_4$ /4.5%  $\text{H}_2\text{O}$  mix, rate constants and activation energies would be different from those of pure hydrazine anyway. Decomposition rates were the same, regardless of whether argon or nitrogen was used to dilute the hydrazine vapor.

The discussion about the validity of Szwarc's results illustrates the difficulty in choosing a proper experimental technique. The Princeton adiabatic flow reactor offers significant advantages over an isothermal reactor but is considerably more complex [348]. It does not suffer from mixing and temperature non-uniformity problems encountered in isothermal bombs and isothermal flow reactors. The adiabatic flow reactor provides data in a reaction rate regime that is too slow for shock tubes and too fast for isothermal bombs. Even in a very comprehensive study, one can read the statement that *"Despite all work done on hydrazine decomposition, the overall mechanism by which this decomposition proceeds is still not understood. For the case of hydrazine derivatives, the situation is even worse"* [348]. In the 58 years since publication of this statement (1964), the reaction has been studied intensively but is still not completely understood, in particular as soon as one leaves the low-pressure regime of a few mm Hg pressure.

The most comprehensive study of thermal gas-phase decomposition of hydrazine and its methyl derivatives was conducted at Princeton University [348, 1209]. The Princeton adiabatic flow reactor was made entirely of quartz to minimize decomposition of hydrazine in the injector portion [348]. In an earlier model with stainless-steel injector and reactor, the hydrazine decomposed prematurely by contact with the walls. The flow conditions were highly turbulent to promote rapid mixing of injected hydrazine with the carrier gas stream to prevent back diffusion. The molar fraction of reactant in diluent helium or nitrogen gas rarely exceeded 0.02. Different duct diameters (7.5 or 10 cm = 3 or 4 in.) were used to vary the heat loss/heat compensation condition and to verify that the system was truly adiabatic. The overall stoichiometry could be described by the following equation:

Similar decomposition product compositions had been observed in flame studies, such as those by [1210] discussed in Section 4.9:

The results of this study show (Figure 39) the rate constants of thermal decomposition of hydrazine and its methyl derivatives as a function of reciprocal absolute temperature. The activation energy can be derived from the slope of the lines.

**Figure 39:** Comparison of decomposition rates of hydrazine, MMH, and UDMH vapor in 76-mm reactor. (Reproduced and modified from [348].)

One seeming contradiction is the fact that the rate constant for UDMH at a given temperature is higher than that of MMH or hydrazine, although in other parts of this book it was stated that the thermal stability of hydrazine increases in the order hydrazine, MMH, and UDMH. Apparently, additional factors become important in the decomposition of hydrazine at higher concentrations than those studied in the Princeton reactor. The decomposition of methylhydrazine will be discussed in the chapter “Methylhydrazine.”

Figure 40 shows that the adiabatic flow reactor and shock-tube results complement each other very nicely and good agreement exists in the overlapping temperature range.

The overall mechanism of hydrazine decomposition can be broken down into the 10 equations that are shown in Table 52 along with the rate constants suggested by Eberstein [348]. All 10 equations were combined in a computer program and solved for temperatures and constant concentrations and for concentrations at constant temperatures. The combined rate of hydrazine consumption agreed well with experimental shock tube and adiabatic flow reactor data.

In interpreting the results of his study, Eberstein [348] cautioned that the assumption of one generally valid reaction order and the application of the relatively simple Arrhenius equation may lead to oversimplification of a complex reaction mechanism. Also, the effect of impurities must be considered. The hydrazine used in his study had a surprisingly high content of ammonia (8.3% NH<sub>3</sub>, 0.5% H<sub>2</sub>O, 0.3% C<sub>6</sub>H<sub>5</sub>NH<sub>2</sub>, 90.9% N<sub>2</sub>H<sub>4</sub>), and one wonders what effect this high initial ammonia concentration might have had on the exhaust composition. In addition, nitrogen (which may have contained traces of oxygen) was used as a carrier gas to dilute the incoming hydrazine vapor and may have contributed to some of the decomposition products. Experiments eliminating any impurities and participation of the carrier gas have been suggested.

**Figure 40:** First-order rate constants for hydrazine vapor decomposition in flow reactors and shock tubes. (Reproduced and modified from [348].)

Amino radical  $\text{NH}_2$  profiles were measured in a discharge flow reactor at ambient temperature by monitoring reactants and products with an electron impact mass spectrometer [1211]. At the low pressures used (0.7 and 1.0 mbar) the gas-phase self-reaction was dominated by a “bimolecular”  $\text{H}_2$ -eliminating exit channel with a rate coefficient of  $k_3$  (300 K) =  $(1.3 \pm 0.5) \times 10^{-12} \text{ cm}^3 \text{ mol}^{-1} \text{ s}^{-1}$  and leading to  $\text{N}_2\text{H}_2 + \text{H}_2$  or  $\text{NNH}_2 + \text{H}_2$ . The heterogeneous recombination reaction along the walls yields  $\text{N}_2\text{H}_4$  molecules.

One of the reactions for hydrazine decomposition is its splitting into two amino radicals. The rate constant for the reverse reaction, the rate of recombination of two amino radicals, was measured in  $\text{CF}_4$ ,  $\text{N}_2$  or Ar carrier gases at  $293 \pm 2 \text{ K}$  over a pressure range of 0.27 to 1.33 kPa (2 to 10 mm Hg) [1212]. The  $\text{NH}_2$  radicals were produced by the 193 nm photolysis of  $\text{NH}_3$  diluted in the carrier gas. The low-pressure rate constant showed a linear dependence on pressure. The slope of the pressure dependence was dominated by a recombination rate constant for  $\text{NH}_2 + \text{NH}_2$  given by  $(8.0 \pm 0.5) \times 10^{-29}$ ,  $(5.7 \pm 0.7) \times 10^{-29}$ , and  $(3.9 \pm 0.4) \times 10^{-29} \text{ cm}^6 \text{ mol}^{-2} \text{ s}^{-1}$  in  $\text{CF}_4$ ,  $\text{N}_2$ , and Ar diluent

**Table 52:** Mechanism of hydrazine decomposition.

| Reaction number     | Reaction                                         | Rate constant                                                    |
|---------------------|--------------------------------------------------|------------------------------------------------------------------|

| (11)                | $^*N_2H_3^* + X \rightarrow ^*N_2H_3 + X^*$      | $k_{11} = 10^{6.5} \text{ cm}^3 \text{ mol}^{-1} \text{ s}^{-1}$ |

Data source: [348]

gases, respectively. The average of the three independent measurements of the sum of the disproportionation rate constants (the zero pressure rate constant) was  $(3.4 \pm 6) \times 10^{-13} \text{ cm}^3 \text{ mol}^{-1} \text{ s}^{-1}$ .

Recombination of two amidogen  $NH_2$  radicals is relevant to hydrazine formation, ammonia oxidation and pyrolysis, nitrogen reduction (fixation), and a variety of other N/H/X combustion, environmental, and interstellar processes. A comprehensive analysis of the  $H_2NNH_2$  potential energy surface was performed using a variety of theoretical methods, with thermochemical kinetic analysis and master equation simulations used to treat branching to different product sets in the chemically activated  $NH_2 + NH_2$  process [426]. Iminoammonium ylide ( $NH_3NH$ ), the less stable isomer of hydrazine, was included in the kinetic modeling of  $H_2NNH_2$  decomposition. A new, low-energy pathway was identified for the formation of  $NH_3$  plus triplet  $NH$ , via initial production of  $NH_3NH$ . This reaction channel resulted in the formation of dissociated products at a relatively rapid rate at even moderate temperatures. Another pathway for the decomposition of activated  $H_2NNH_2$  eventually leads to the formation of the simple products  $N_2 + 2H_2$  via  $H_2$  elimination to *cis*- $HN=NH$ . This process, referred to as “dihydrogen catalysis,” may have significant implications in the formation and decomposition chemistry of hydrazine and ammonia in diverse environments. In this mechanism, stereoselective attack of *cis*- $HN=NH$  by molecular hydrogen results in decompo-

sition to  $N_2$  with a fairly low barrier. The reverse termolecular reaction leading to the gas-phase formation of  $cis\text{-HN=NH} + H_2$  achieves non-heterogeneous catalytic nitrogen fixation with a relatively low activation barrier ( $322\text{ kJ/mol} = 77\text{ kcal/mol}$ ), much lower than the  $523\text{ kJ/mol}$  ( $125\text{ kcal/mol}$ ) barrier reported for bimolecular addition of  $H_2$  to  $N_2$ .

The recombination rate constants for the reactions  $NH_2 + NH_2 \rightarrow N_2H_4$  (reaction  $k_1b$ ) and  $NH_2 + H \rightarrow NH_3$  (reaction  $k_2b$ ) with  $N_2$  as a third-body have been measured as a function of temperature and pressure in a temperature range of 292 to 533 K and a pressure range of a few mm Hg up to 40–53 kPa (300–400 mm Hg), well within the pressure fall-off region [1213]. The  $NH_2$  radicals were produced by 193-nm pulsed-laser photolysis of  $NH_3$  in a temperature-controlled flow chamber. The pressure and temperature dependence of  $k_1b$  could be represented by a group of parameters.

If hydrazyl radicals exist as intermediates in the hydrazine decomposition, they themselves will soon undergo further decomposition, and attempts were made to obtain a rate constant for this process [1214].

#### 4.4.3 Water Vapor as Inhibitor of Hydrazine Decomposition

Another common contaminant or sometimes a desirable additive to hydrazine is water. The effect of water on the rate of decomposition has been studied repeatedly [348, 1215]. It was found that the rate of decomposition of hydrazine/water mixtures (25%  $H_2O$  and 50%  $H_2O$ ) was 10 times slower than that of anhydrous hydrazine [348]. Surprisingly, it is independent of the amount of water added. The 25 and 50%  $H_2O$  mixtures behaved kinetically like wet hydrazine samples with 0.8 or 0.9%  $H_2O$ , respectively.

It was noted that wet hydrazine and hydrazine/water mixtures decompose at a rate that appeared to be independent of the surface:volume ratio. The effect of water on the decomposition rate goes beyond that of a simple diluent and would indicate some kind of inhibition on a rate-determining step. It has been hypothesized that water is 100 times more active in absorbing vibrational energy from vibrationally excited species with which it collides than, for example, nitrogen. Water has more freedom of vibration and, if colliding with an activated  $N_2H_3^*$  radical or  $N_2H_4^*$  molecule that otherwise would decompose forming chain-propagating  $^{\bullet}NH_2$  radicals, will deactivate that molecule or radical.

#### 4.4.4 Inhibiting Effects of Permanent Gases

The decomposition of hydrazine vapor in equilibrium with hydrazine liquid and the effect of hydrogen, nitrogen, or argon on the decomposition limits were studied in a glass apparatus using electrical arc ignition with tungsten electrodes [1216]. Decomposition flames were obtained in saturated vapor above 310 K, corresponding to a vapor pressure of 3.16 kPa (23.8 mm Hg). For unsaturated conditions, the threshold

pressure increased with temperature, which is somewhat surprising since the opposite trend should be expected from kinetic data. Of the three gases evaluated as potential decomposition-inhibiting blanketing gases for hydrazine distillation, hydrogen was the most active, nitrogen intermediate, and argon the least active diluent. The difference in activity is thought to be related to their heat capacity, not a kinetic interaction with the decomposition mechanism.

#### 4.4.5 Inhibiting Effects of Organic Vapors

In a similar way, organic vapors were tested as additives in a decomposition apparatus [1217]. The vapor concentration of additive above which hydrazine vapor mixtures will not decompose explosively decreases in the order argon (71.9), nitrogen (64.8), hydrogen (45.9), benzene (27.9), toluene (24.0), xylene (20.0), butane (17.3), hexane (12.8), and heptane (11.9). Organic vapors are thus more effective at suppressing hydrazine vapor decomposition than are inorganic gases. Aniline was also tested, but its effectiveness depended on the total pressure in the system because its boiling point is so different from that of hydrazine. Heptane is a useful blanketing fluid for the distillation of anhydrous hydrazine. Additional studies on the effect of diluents and inhibitors on the explosive decomposition limits of hydrazine vapors are discussed in Section 8.4.2. These tests relate more to the handling safety of hydrazine than to the elucidation of the decomposition mechanism of hydrazine, to which this chapter is devoted.

Subsequent investigators have analyzed Eberstein's data and attempted to fit them to their own kinetic models (in particular those providing overall kinetics) and tried to expand the range of validity of kinetic equations to higher hydrazine partial pressures up to atmospheric [1218]. Using an asymptotic analysis based on large differences among the rate constants of several elementary reactions, it was shown that the Eberstein-Glassman mechanism for the thermal decomposition of hydrazine could be expressed by an overall rate equation between 750 and 1000 K. Data on the rate constants of homogeneous hydrazine decomposition are summarized in Table 53. Depending on the technique used, the results differ widely, even in the assignment of a reaction order for the global decomposition rate equation. At high pressure, the activation energy seems to be on the order of 225 kJ/mol.

#### 4.4.6 Isotope Effects on the Decomposition of Hydrazine

A study on the thermal decomposition of  $^{15}\text{N}$ -labeled hydrazine was somewhat hampered by the fact that the  $^{15}\text{N}$  isotope concentration in the starting material was only 32% [1224]. The results agree with a later study on the photolysis of hydrazine [1153] in that in neither case was randomization of nitrogen observed. Kant and McMahon [1224] share the opinion of Szwarc [1200] that free radicals are not involved in the thermal decomposition of hydrazine. Since it is very difficult to eliminate the effects of the surface of the reaction vessel, at least part of the thermal decomposition of hydrazine

**Table 53:** Rate constants of homogeneous hydrazine decomposition.

| Reaction                                                                                                   | Rate constant <i>k</i>                                                              | References |

<sup>a</sup> All activation energies in cal/mol.<sup>b</sup> It appears that the gas constant *R* has already been factored into the denominator

may proceed by means of a heterogeneous surface reaction. If it did proceed through the following sequence of reactions,

complete randomization of nitrogen would have to be expected. Instead, the non-occurrence of randomization was temporarily explained by a transition complex involving three hydrazine molecules, from which nitrogen would evolve without breaking an N—N linkage.

The dashed lines in the following scheme indicate the fashion in which this transition complex would break up. An arrangement of this kind would be achieved only on surfaces, not in the gas phase. If randomization had been observed, it would be important to know whether it occurred during hydrazine decomposition or was a reaction that dinitrogen molecules underwent after they were formed. However, dinitrogen molecules are thermally very stable, and nitrogen isotope randomization can be achieved only at temperatures above 970 K.

At the time of that study, the ratio of disproportionation : recombination of hydrazyl radicals according to

was not yet known. Later photolytic studies have shown that this ratio is surprisingly high and accounts for the non-randomization, even though hydrazyl radicals are involved [1152]. The ratio of disproportionation : recombination of hydrazyl radicals was found to be approximately four. To explain this mechanism, it is necessary to assume that two hydrazyl radicals must collide in the proper sterical arrangement for the disproportionation to take place. The mechanism may also be favored by an (only transient) stability of an intermediately formed tetrazane. Nevertheless, it is more likely to have two hydrazyl radicals in proper arrangement than three hydrazine molecules, as postulated by the Szwarc surface mechanism. The ratio of disproportionation to combination for hydrazyl radicals is nearly 30 times larger than that for the analogous  $^{\bullet}\text{C}_2\text{H}_5$  radical.

A transition or hybrid mechanism between thermal and photolytic decomposition has been postulated for the flash photolysis of hydrazine [521, 1225]. The high-intensity flash was only used to raise temperature of the vapor rapidly to a desired decomposition temperature, and short wavelengths were filtered out. With this method, undesirable interference by hot surfaces can be eliminated. The conversion is small, generally below 10%, as opposed to thermal experiments, which usually allow the decomposition to go to completion.

The decomposition of  $^{15}\text{N}$ -isotope-labeled hydrazine by flash photolysis showed that no nitrogen randomization occurred and the yield of  $^{14}\text{N}^{15}\text{N}$  was very low [1226]. This agrees with previous thermal [1224] and photolytic [1153] isotope studies and heterogeneous decomposition results discussed in Sections 4.6.1 and 4.6.4. It has also been observed that the ratio of hydrogen : nitrogen was always close to 1.0. This can be explained by assuming that hydrogen and nitrogen are formed by the decomposition of diazene:

while at the same time maintaining the isotope distribution in nitrogen. The  $\text{N}_2$  formed by the flash photolysis of hydrazine was found to be only 17% randomized (compared to 13% for photolytic decomposition). An excess of  $^{14}\text{N}_2$  formed in the decomposition of 1:1 mixtures of  $^{14}\text{N}_2\text{H}_4$  and  $^{15}\text{N}_2\text{H}_4$  remained unexplained. The photolysis of hydrazine at 133 Pa (1 mm Hg) in a 75-mL cylindrical quartz vessel with a single jolt of 720 J resulted in the decomposition of approximately 10% of the hydrazine present [1153, 1227].

Besides isotope labeling, the addition of radical scavengers sometimes provides insight into the radical mechanisms of thermal as well as the photolytic decomposition of hydrazine. Most studies of this type have been conducted in relation to the photolysis of hydrazine, but it was also used to study the slow thermal decomposition of hydrazine vapor [1228]. The decomposition rate of  $\text{N}_2\text{D}_4$  has been shown to be markedly different from that of  $\text{N}_2\text{H}_4$  as a result of the isotope effect [1154].

#### 4.4.7 Effects of Wall Materials on Decomposition of Hydrazine

It would be important to find wall materials that will not only not catalyze the decomposition of hydrazine but even retard the unwanted decomposition that may occur when hydrazine is distilled. The effect of various reaction vessel materials and surface coatings on the thermal decomposition of hydrazine was studied in an early investigation [1229–1231]. Calcium oxide and cadmium sulfide increased the rate of decomposition between 570 and 770 K in a flow system more than did Pyrex. A zinc oxide/potassium hydroxide/water glass surface acted like uncoated Pyrex glass. A mixture of aniline and toluene has been suggested as additive to inhibit the unwanted thermal (homogeneous) or catalytic (heterogeneous) decomposition of hydrazine vapor during hydrazine manufacturing operations [1232, 1233].

#### 4.4.8 Diazene as Intermediate in Hydrazine Decomposition

A complete understanding of the decomposition of hydrazine must include the nature of the intermediates that play a role in the decomposition mechanism. Obviously, many nitrogen-hydrogen free radicals and short-lived molecules, such as diazene, play an important role in the decomposition of hydrazine, regardless of whether it is initiated thermally, photolytically, or by any other means. The same is true for the oxidation of hydrazine in both gas phase and solution. Several publications deal with the properties of these radicals and short-lived molecules regardless of their path of formation or decay. Some of these papers are referenced here because they may aid the more seriously interested reader in locating additional information on hydrazine formation and decomposition and its intermediates such as imidogen NH radicals [1234, 1235] or hydrazido  $\text{N}_2\text{H}_3$  radicals [1053, 1236].

Trying to find hydrazine in ammonia-laden interstellar or planetary environments may not be possible by detecting hydrazine itself but only its fragments that are re-

leased following a short-lived existence and inevitable decomposition. One can only indirectly prove that hydrazine may have existed in those mixtures of decomposition products, including ammonia and diazene.

Most of the earlier studies on diazene as an intermediate in hydrazine decomposition were done in the liquid phase. One study identified diazene as an intermediate of the thermal, surface-catalyzed gas-phase decomposition of hydrazine or ammonia at 180–500 K on polycrystalline rhodium foil [1237, 1238]. They identified diazene based on mass spectrometry of the parent ion at 30 amu and a single-dehydrogenation fragmentation product at 29 amu that is present at 6% of the abundance of its parent. Adsorbed NH was proposed as an intermediate residing on the surface. Co-adsorption of hydrogen increased and co-adsorption of oxygen decreased the diazene yield.

In the gas phase, diazene decomposition showed a first-order dependence on the concentration of diazene,  $k_{\text{obs}} = 2.45 \times 10^{-3} \text{ s}^{-1}$  at 296 K (23 °C) [1239]. A rate-limiting step in this mechanism may be the *trans*-*cis* isomerization (illustrated in the following schematic Figure 41, patterned after a similar schematic in [1240]).

**Figure 41:** Competitive pathways in gas-phase decomposition of diazene

The reactive *cis*-diazene interacts with another *trans*-diazene via a cyclic  $\text{N}_4\text{H}_4$  intermediate (“diazene dimer”) to form either nitrogen and hydrogen with the restoration of some of the diazene (left pathway) or hydrazine and nitrogen (right pathway). The difference between the two ring structures is the orientation of the *cis* member, one facing the nitrogen atoms, the other facing the hydrogen atoms and allowing some hydrogen bridging. Although *trans*-diazene is thermodynamically unstable, its symmetry provides it some stability advantages and less reactivity compared to the *cis* isomer. The thermal decomposition of  $\text{N}_2\text{H}_2$  and  $\text{N}_2\text{D}_2$  follows a single first-order ki-

netic rate equation for most temperature and pressure conditions [1241]. It was suggested that the rate-determining step in the mechanism is a first-order homogeneous gas-phase isomerization of *trans*-diazene. The *trans* isomer is sterically hindered and less reactive than the *cis* isomer. Diazene decomposition usually leads to isomerization to the more reactive *cis* isomer first. The decomposition reaction shows a distinct isotope effect as shown below:

$$k(\text{N}_2\text{H}_2) = 1.8 \exp\left(\frac{-4.2}{RT}\right) \quad k \text{ in s}^{-1}, E_a \text{ in kcal/mol}$$

$$k(\text{N}_2\text{D}_2) = 1.0 \exp\left(\frac{-4.4}{RT}\right) \quad k \text{ in s}^{-1}, E_a \text{ in kcal/mol}$$

At temperatures above room temperature, self-heating leads to rapid run-away decomposition.  $\text{N}_2\text{H}_2$  decomposes to  $\text{N}_2$ ,  $\text{H}_2$ , and  $\text{N}_2\text{H}_4$ , whereas  $\text{N}_2\text{D}_2$  gives mostly  $\text{N}_2$  and  $\text{N}_2\text{D}_4$ . Azide or ammonia could not be detected at the detection limit of the methods used. The concentrations of  $\text{N}_2\text{H}_2$  and  $\text{N}_2\text{D}_2$  can be determined by measuring the absorption at 365 nm, and the optical density follows Beer's law at concentrations between 0.1 and 1.2 mMol/L. A calibration chart was provided by Willis, Back, and Purdon [1241].

The reaction of *cis*- or *trans*-diazene with dihydrogen leads back to hydrazine, but the stereoisomers react at different speeds. *Ab initio* calculations of the reactants and transition states have enabled us to predict kinetic barriers for this reaction [1242].

Diazene is often observed as an intermediate in the oxidation or decomposition of hydrazine. It can be easily characterized by its distinct absorption spectrum in the near UV. It can be trapped on a cold finger extending into a hydrazine decomposition chamber, e.g., a glow discharge. A convenient method to study the spectra of diazene at leisure without having to worry about premature decomposition is by trapping it in liquid ammonia. The near-UV absorption spectrum of diazene in liquid ammonia at 220 K is shifted by 50 nm to the long end of the wavelength scale compared to the gas-phase spectrum of diazene with a  $\lambda_{\text{max}}$  at 400 nm [440]. The spectrum in the liquid state is also broadened and the vibrational structure is largely obscured, most likely as a result of hydrogen bonding. Diazene decay in liquid ammonia follows a first-order kinetic rate equation  $r = 1.9 \times 10^3 \exp(-6.6/RT) \text{ s}^{-1}$  with an activation energy of 6.6 kcal/mol.

The thermochemical and kinetics properties of the hydrogen abstraction and addition processes of the *trans*- $\text{N}_2\text{H}_2 + \text{N}$  reaction were computed using high-level *ab initio* and DFT approximation methods [1243]. The results for classical barrier height were 54.8 and 62.8 kJ/mol (13.1 and 15.0 kcal/mol) for the abstraction and addition reactions, respectively. The thermal rate constants were calculated using the dual-level direct dynamics by variational transition state theory with the potential energy surface and thermochemical properties corrected. The calculated rate constants showed that the variational and tunneling effects play a relevant role only for the abstraction reaction.

#### 4.4.9 Tetrazane as Intermediate in Hydrazine Decomposition

The recombination of two hydrazyl free radicals forms tetrazane,  $N_4H_6$ . This is similar to tetrazene(2)  $N_4H_4$  with a double bond at the center of the molecule, which may be more stable than tetrazane. A yellow material was detected in the condensate that was flash frozen from thermally decomposing hydrazine onto a liquid-nitrogen-cooled finger [1207, 1244]. It was suggested that this material, which decomposed on warming, is tetrazane,  $N_4H_6$ . The gas evolved when the yellow material decomposed at 95 K was mainly (98.5%) nitrogen. This could indicate that the material is not amino radical  $\bullet NH_2$  or hydrazyl radical  $\bullet N_2H_3$ . This is also supported by the fact that the sample was not paramagnetic as would be expected from free radicals. The half-life of the yellow compound is on the order of 9 ms, much longer than that of other species, such as  $NH$ ,  $\bullet CH_3$ , or  $|CH_2$ . There have also been attempts to identify the mechanism of  $N_4H_6$  formation using  $^{15}N$ -labeled hydrazine. However, the low isotope content in the starting material and partial randomization made an interpretation of the results very difficult.

#### 4.4.10 Decomposition of Hydrazine in Shock Tubes

Shock-tube studies are well suited for the study of hydrazine decomposition kinetics. With a proper selection of experimental conditions, certain fast phenomena can be separated and studied individually. Thus shock-tube studies are for thermal decomposition what short-wavelength flash photolysis is for photolytic decomposition. The shock-tube technique allows a sample to be rapidly heated to a high temperature, held there for a few milliseconds, and then rapidly cooled by adiabatic expansion. During the short hot period, the decomposition is truly homogeneous without interference from heterogeneous wall reactions. Shock tubes typically consist of a high-pressure driver section filled with helium and a low-pressure test section, which is filled with the gas (vapor) under study. A small intermediate chamber, separated from either section by coined burst discs, can be rapidly evacuated, resulting in the rupture of the burst disc and release of a plane shock wave into the test section. The incident shock wave raises the temperature and pressure of the test gas instantly. The incident shock wave is reflected at the planar end of the shock tube and, in passing through the once-shocked medium in the opposite direction, again raises the temperature of the medium incrementally to an even higher temperature and pressure. The temperature and pressure behind the reflected shock wave remain constant for several hundred milliseconds, during which time period kinetic studies are carried out. Shock-tube decomposition studies with hydrazine have been conducted by numerous investigators during the past seven decades.

The temperatures achieved in a shock tube are significantly higher than those in externally heated devices. Nevertheless, good agreement has been obtained, for instance when comparing the results from an adiabatic flow reactor with those obtained in a shock tube (Figure 40 above).

The diagnostic methods of observation of the decomposition processes in shock tubes include schlieren photography, pressure transducers, mass spectrometers [1245, 1246]; UV absorption at 2300 Å [1195, 1220]; or NH radical emission spectrophotometry [1247, 1248].

One of the first shock-tube studies of hydrazine decomposition conducted in the United States was the one at Rocketdyne [1193]. The amount of decomposition and the composition of the reaction products was determined by drawing a gas sample into an evacuated flask immediately after passage of the shock wave. The gas sample was then analyzed in a mass spectrometer. It was assumed that no further change of composition occurred after the sample gas was transferred into the evacuated flask. The stoichiometry of the decomposition under these conditions could be expressed by

Moberly believed that his results supported a steady-state chain mechanism such as the one proposed by [1249]. Because many of the individual rate constants of reaction steps in this mechanism were not yet known in 1962, Moberly [1193] could not check his assumption against the global rate, which he had just measured and found to be

$$k = 10^{10.73} e^{\frac{-37500}{RT}} \text{ s}^{-1}$$

assuming a reaction of 1.5 order with a termolecular termination step. (From today's viewpoint, quite improbable). This assumption has not been confirmed by later investigators. It was expressly stated that this method of deciding on a reaction mechanism was very crude and could be taken only as a guess and that more work needed to be done to define the mechanism more precisely.

A study of the decomposition of hydrazine vapor diluted with argon at 1200–2500 K and 4.04–25 kPa (0.04–0.25 atm) total pressure in a shock tube used a TOF mass spectrometer to track the concentration of reactant, intermediates, and products [1245, 1246]. The time-resolved (25 μs) mass spectra showed the sequence of events as a shock wave passed through the gas. The major species observed were N<sub>2</sub>H<sub>4</sub>, NH<sub>3</sub>, N<sub>2</sub>, H<sub>2</sub>, and the •NH<sub>2</sub> free radical. The primary process in the dissociation of hydrazine was shown to be the rupture of the N–N bond to give •NH<sub>2</sub> radicals. The •NH<sub>2</sub> free-radical concentration was found to go through a maximum and then to decay within the same time as hydrazine. No radicals other than •NH<sub>2</sub> were observed. The rate constants measured by Diesen disagreed with the rate constant measured by Szwarc for thermal decomposition of hydrazine in toluene vapor [1200].

A controversy had developed at one time over the interpretation of hydrazine shock-tube data obtained by different groups. Michel and Wagner [1195, 1250, 1251] proposed a chain mechanism, whereas McHale [352, 353] claimed a simple non-chain mechanism. The first group (Michel and Wagner 1962–1965) studied the thermal decomposition of highly diluted hydrazine (0.03–0.5% N<sub>2</sub>H<sub>4</sub> in Ar or He) behind shock waves at temperatures of 1100–1600 K. At low temperatures and high concentrations, an induction period and a dependence of the half-lives of N<sub>2</sub>H<sub>4</sub> on the concentration

was observed, which is usually characteristic of chain reactions. The pyrolysis of ammonia was also investigated in the same apparatus to determine how the hydrazine decomposition product composition could be altered by undesirable post-shock reactions. The addition of oxygen to a 0.3% hydrazine/argon mixture did not cause significant acceleration unless the oxygen : hydrogen equivalence ratio exceeded two.

In continuation of these studies, a new shock tube was built at Göttingen, and the rate of decomposition of hydrazine at concentrations of  $2 \times 10^{-6}$  to  $3 \times 10^{-6}$  mol cm<sup>-3</sup> was measured at low and high pressures, also in comparison to that of ammonia [1252]. The effect of boundary-layer phenomena on the conditions behind the incident and reflected shock waves was also taken into consideration. The NH<sub>2</sub> and NH concentration profiles were measured as a function of time. The constants for low- and high-pressure decomposition of hydrazine are summarized in Table 54.

**Table 54:** Rate constants of hydrazine and ammonia decomposition in shock waves.

| Reactant  | Pressure regime | Rate equation         |                           |
|-----------|-----------------|-----------------------|---------------------------|
|           |                 | Pre-exp. factor       | Activation energy, kJ/mol |
| Hydrazine | Low             | $6.5 \times 10^{-17}$ | 233                       |
| Hydrazine | High            | $2.5 \times 10^{-16}$ | 281                       |
| Ammonia   | Low             | $4.0 \times 10^{-16}$ | 393                       |
| Ammonia   | High            | $5.5 \times 10^{-15}$ | 451                       |

Data source: [1252]

This work gave an enthalpy of formation for the amidogen radical of 196 kJ/mol, which was quite different from the one listed in the JANNAF tables (+167.8 kJ/mol). Perhaps the authors meant the formation of amidogen from hydrazine and not from the elements [1252]. The formation and decomposition of NH<sub>2</sub> and NH radicals as well as H and N atoms during the thermal decomposition of hydrazine in shock tubes was investigated over a wide temperature range [1253]. The decomposition of hydrazine already started behind the incident shock wave. For the first time frequency-modulated spectroscopy was used for the detection of NH<sub>2</sub> radicals behind shock waves. In comparison with the dual beam laser absorption technique, the detection limit was improved by 1.5 orders of magnitude. A premixed oxygen/ammonia flame was used as a stationary, constant source of NH<sub>2</sub> and NH radicals and the reference beam of a dual-beam laser absorption spectrometer passed through it. The rate constants are summarized in Table 55.

The experimental apparent activation energies were found to be in good agreement with theoretical calculations and recommended enthalpies of formation for NH<sub>2</sub> and NH. The competing NH<sub>2</sub> decomposition channel

**Table 55:** Rate constants of  $\text{NH}_2$  and  $\text{NH}$  decomposition.

| Reaction                                                             | Temp. range, K | Rate constant $k$                                                                                                |

Data source: [1253]

was shown to be only of minor importance ( $\leq 5\%$ ). The publication contains an up-to-date summary of 26 reactions of  $\text{NH}$  species involved in the decomposition of hydrazine listing the pre-exponential factors  $A$ , reaction orders  $n$ , and activation energies  $E_{\text{act}}$  of these reactions, along with literature references [1253].

The results by McHale and co-workers [352, 353] contradicted those of Michel and Wagner and many other researchers. It was generally accepted as an almost undisputed fact that the decomposition of hydrazine proceeds by way of a chain mechanism. However, in many cases this assumption was adopted by some authors without experimental verification of their own. Similar errors such as the true mechanism of the iodine plus hydrogen reaction have perpetuated themselves over decades until some probing independent researcher took an unbiased approach. The same might be true for hydrazine. In view of this, the study by McHale deserves special attention. The experimental study used a single-pulse shock tube at 970–1120 K and 232–867 kPa (2.3–8.6 atm) with approximately 1 mol-% hydrazine in argon. Comparing the experimental conditions of the two conflicting studies side by side, the latter used lower temperatures over a narrower range of temperatures. The hydrazine concentrations were higher than those used by anyone else in shock-tube studies. This may be one of the reasons why the experimental results led the authors to the conclusion that the decomposition kinetics obeyed a simple non-chain mechanism. Possible chain mechanisms (mainly those proposed by Adams and Stocks) were examined in detail and found to be at variance with observations.

McHale's review of previous data is repeated here because it will aid in the subsequent discussion of advantages and disadvantages. There is hardly any discussion on hydrazine decomposition without reference to Szwarc's historical determination of the N–N dissociation energy [1200]. As discussed in Section 4.4.1 on thermal decomposition,  $\text{D}(\text{H}_2\text{N}–\text{NH}_2)$  was first determined by Szwarc to be 251 kJ/mol (60 kcal/mol). A re-evaluation of these data by Gilbert [1202] resulted in a significantly higher pre-exponential factor

$$k_1 = 10^{19} e^{\frac{-60000}{RT}}$$

If Gilbert's revision is correct, the activation energy, which should be close to the N–N dissociation energy, would have to be 305 kJ/mol (73 kcal/mol), which is excessively high compared to the  $243 \pm 37$  kJ/mol ( $58 \pm 9$  kcal/mol) found by Foner and Hud-

son [342]. In the opinion of McHale, the results obtained by Szwarc are dubious because heterogeneous decomposition was not prevented.

One interesting way to relate bond dissociation energies and activation energies with the molecular structure of hydrazine is to study the number of classical oscillators required to absorb the energy prior to dissociation. Each of these oscillators represents one internal degree of freedom and thus contributes  $0.5R$  to the heat capacity of the molecule. The total number of possible internal (valence and deformation) oscillations in hydrazine is 15. These considerations are also important for the interpretation of IR spectra (Section 2.4.2). McHale used the number of oscillators to assess the acceptability or impossibility of N–N dissociation energies proposed in the literature. His results indicate that  $D(\text{H}_2\text{N}–\text{NH}_2)$  is 226 kJ/mol (54 kcal/mol), and the unimolecular theory predicts that six classical oscillators contribute energy to the low-pressure decomposition. An activation energy of about 151 kJ/mol (36 kcal/mol) is predicted for the second-order reaction at 2000 K, in agreement with results by Allison in hydrazine liquid strand burning flames, that is, 167 J/mol = 40 kcal/mol [1254].

McHale and co-workers studied the effect of contaminants, water and carbon dioxide, on the rate of decomposition of hydrazine in a shock tube [352, 353]. Up to 3%  $\text{H}_2\text{O}$  or 1%  $\text{CO}_2$  had no measurable effect on the rate of decomposition. However, the discrepancy between their 1965 results and those of a previous investigation by one of the authors using the same apparatus [1255] was explained as being caused by impurities in the hydrazine. The rates differed by a factor of two depending on the method of drying the hydrazine,  $\text{CaH}_2$  distillation, or  $\text{CaH}_2$  distillation followed by passing the vapor through a molecular sieve Linde 3A column [99].

The advantage of shock-tube studies is that they can be performed over a wide range of pressures. The initial reactions can be studied free from interference from consecutive reactions. However, at low temperatures ( $<1200\text{ K}$ ) and high hydrazine concentrations ( $>10^{-7}\text{ mol/cm}^3$ ) evidence for a chain mechanism has been assumed in view of the induction periods observed [1195]. It is very difficult to interpret results because the order of

changes markedly with pressures between 0.1 and 1 MPa.

The previous measurements by the Göttingen group were extended over a wider range of pressures [1220]. Experiments at low pressure were conducted with incident shock waves and argon dilution at 0.2–0.5% hydrazine in argon and a total pressure of 20–404 kPa (0.2–4 atm). The temperature in the shock front was 1280–1580 K. The hydrazine concentration was measured by its UV absorption at 230 nm. Under the conditions used, the rate equation for hydrazine decay was

$$k = 10^{15.6} e^{\frac{-41000 \pm 2000}{RT}}$$

This agrees well with other data [1245, 1246]. At high pressures (up to 30.3 MPa = 300 atm), more dilute hydrazine mixtures (0.001–0.1%) in argon were used to avoid

interference from the heat of reaction. The experimental first-order rate constants were found to be independent of the total pressure above 30.3 MPa (300 atm); the equation is

$$k_1 = 10^{13.7} e^{\frac{-54000 \pm 2000}{RT}}$$

At low pressure the rates fall off, and the fall-off curves ( $k$  vs.  $p$  with temperature as auxiliary parameter) are plotted in [1220] for these most recent data in comparison with data obtained from [353, 1052, 1195, 1245, 1246].

It was previously assumed that thermal hydrazine decomposition occurred through splitting into two amino radicals, similar to radiolysis [1220, 1256]:

However, this opinion had to be revised in view of other results [1196]. Based on unimolecular decomposition rates, a reaction enthalpy of 243 kJ/mol = 58 kcal/mol had to be assumed. However, a reaction by way of

would be more favored because it requires only a reaction enthalpy of approximately 188 kJ/mol = 45 kcal/mol. So far, ammonia and imino radicals were thought to be secondary rather than primary products of hydrazine decomposition. The enthalpy of formation of NH was determined by an independent method to be 197 kJ/mol (47.2 kcal/mol) [1206]. With this revised value,  $\Delta H$  of

would be 301 kJ/mol (72 kcal/mol), making it even less likely than before.

In three tests with 1% hydrazine in nitrogen at 1100 K/296 kPa, 1160 K/275 kPa, and 1190 K/220 kPa, induction periods were observed only at the two lowest temperatures [1192, 1257]. The induction period was not noticeable at 1190 K, about 50  $\mu\text{s}$  at 1160 K, and a little less than 200  $\mu\text{s}$  at 1100 K. For mixtures containing less than 2 mol-%  $\text{N}_2\text{H}_4$ , pressures above 500 kPa, and shock temperatures between 1100 and 1400 K, the rate constant was expressed as

$$k = (1.9 \pm 0.2) 10^{12} e^{\frac{-22900 \pm 500}{T}} \quad k \text{ in units of } \text{s}^{-1}, T \text{ in K}$$

Differences between more concentrated and more diluted mixtures of  $\text{N}_2\text{H}_4$  vapor in  $\text{GN}_2$  become more obvious at higher temperatures. The energy contribution from the decomposition in more concentrated mixtures increases the temperature and the system is no longer isothermal. With more concentrated mixtures between 1090 and 1400 K and for pressures above 500 kPa, the kinetic rate constant can be approximated by

$$k = (1.2 \pm 0.7) 10^{14} e^{\frac{-27600 \pm 700}{T}} \quad k \text{ in units of } \text{s}^{-1}, T \text{ in K}$$

Some of the nitrogen diluent in mixtures containing 0.5–2%  $\text{N}_2\text{H}_4$  was substituted with 20, 40, and 60% helium. The rate constants derived from the Arrhenius plots were

$$k = (4.5 \pm 1)10^{11} e^{\frac{-21300 \pm 700}{T}} \quad \text{for 20–40\% He}$$

$$k = (2 \pm 0.3)10^{11} e^{\frac{-20500 \pm 600}{T}} \quad \text{for 60\% He}$$

where  $k$  is the reaction constant in  $\text{s}^{-1}$  and  $T$  is the temperature in kelvin. The diameter of shock tubes is usually chosen well above the critical diameter below which detonations can no longer propagate through narrow tubes. The dynamic parameters of detonations are as follows:

- Critical detonation initiation energy  $E_c$
- Critical diameter  $d_c$ , corresponding to minimum diameter of a tube necessary to achieve propagation
- Characteristic dimension  $\lambda$  of detonation cells

Several empirical equations have been derived for all vapor detonations (not only for hydrazine) to correlate these parameters:  $E_c$  is roughly proportional to the cube of the cell diameter:

$$E_c \sim \lambda^3$$

the critical diameter is approximately 13 times the cell diameter:

$$d_c \sim 13\lambda$$

and the cell diameter is approximately 29 times the length of the induction zone  $\Delta$ :

$$\lambda \sim 29\Delta$$

The cell diameter can be measured by depositing a thin layer of soot on the inside of the detonation tube. The passage of the detonation wave leaves a pattern of diamond-shaped crisscrossing lines where the high pressure has lifted the soot off the wall. It can also be measured by an optical method.

The detonation velocity and cell widths for hydrazine decomposition were measured over a wide range of temperatures and pressures [1258]. The detonation velocity in pure hydrazine vapor was within 5% of the calculated Chapman-Jouguet (C-J) velocity. The detonation cell width measurements were interpreted using the Zeldovich-von Neumann-Doring (ZND) model with a detailed reaction mechanism for hydrazine decomposition. Agreement with experimental data for pure hydrazine was obtained using the empirical relation that detonation cell width was equal to 29 times the kinetically calculated reaction zone length. Figure 42 presents the NASA WSTF data, showing the cell diameter of hydrazine as a function of the pressure with temperature as the auxiliary parameter. The cell diameter  $\lambda$  of hydrazine vapor detonations at 101 kPa and 393 K was extrapolated from low-pressure data to be 1.38 mm, a very, very small number indeed. The format in Figure 42 is like that derived by [1259].

**Figure 42:** Detonation cell width as a function of hydrazine vapor initial pressure. (Reproduced and modified from [1258], with permission from ©1988 American Institute of Aeronautics and Astronautics 7-Jul-2021.)

The cell diameter is typically predicted to be  $\lambda = 29\Delta$ , where  $\Delta$  is the length of the induction zone. These data are in good agreement with predicted theoretical numbers. The reaction zone length  $\Delta$  of the traveling detonation wave is dependent on the induction time. The pressure dependence of the reaction zone length illustrated in Figure 43 suggests that

$$\Delta \approx p^{-0.8}$$

It was mentioned previously that empirical correlations for most gas detonations put the dependence of the critical tube diameter on the detonation cell width at

$$d_c \sim 13\lambda$$

This correlation is shown as a straight line in Figure 43, and data points fall not too far from this line.

Hydrazine vapor detonation data were obtained at NASA in an 150-mm-ID, 1.75-m-long stainless-steel tube with 7-mm-thick walls [1258]. The chamber could be evacuated, injected with liquid hydrazine, and heated to evaporate all the hydrazine. Two methods of initiation were used in these tests: For initial studies at higher pressures, an oxygen-acetylene driver section was used. For later tests, in particular those at lower pressures, hydrazine vapor ignition was achieved by a spark gap through which a capacitor bank holding up to 3 kJ was discharged. This initiation was faster and more reproducible than the acetylene driver. Detonation velocity and pressure was measured with four piezoelectric transducers at 0.4-m intervals along the tube. Detonation velocities (e.g., 2406 m/s at 60 kPa) were within  $\pm 10\%$  of the calculated velocity

**Figure 43:** Calculated reaction zone lengths for pure hydrazine vapor as a function of initial pressure. (Reproduced and modified from [1258], with permission from ©1988 American Institute of Aeronautics and Astronautics 7-Jul-2021.)

using the C-J equation. Other measured data (cell diameter) were in good agreement with predictions made with the ZND model described by Shepherd.

Shock-tube measurements of hydrazine decomposition were extended to high pressures and measurement of decomposition behind the reflected shock wave [1197]. The rate equation for the decomposition of 0.01–0.1% hydrazine vapor in argon at 10.1–30.3 MPa (100–300 atm) was very similar to that derived by previous authors [1220]:

$$k_1 = 10^{13.6 \pm 0.4} e^{\frac{-53000 \pm 2000}{RT}} \text{ s}^{-1}$$

For additional shock-tube studies on hydrazine decomposition, see [1198, 1260]. Similar data are available on the decomposition of methylhydrazines in shock tubes (Chapter “Methylhydrazine”).

The addition of NO as a radical scavenger was expected to facilitate the clarification of the dispute between promoters of free-radical chain mechanisms in the decomposition of hydrazine vapor. If the reaction proceeded through

then a noticeable effect on the kinetic rate should be observed because NO reacts with  $\bullet\text{NH}_2$  more rapidly than  $\bullet\text{NH}_2$  does with hydrazine:

If hydrazine decomposed through

the intermediate NH would react with NO and form  $\text{N}_2\text{O}$ :

Amino radicals would also react quickly with NO:

and NO addition should slow down the reaction if amino radicals play a key role. The results obtained in a shock tube showed that the rate of hydrazine decomposition in a wide range of  $\text{N}_2\text{H}_4:\text{NO}$  ratios was indeed independent of NO addition, which speaks against the intermediacy of  $\cdot\text{NH}_2$  [1196]. The main products were  $\text{N}_2\text{O}$  and  $\text{NH}_3$ , whereas  $\cdot\text{NH}_2$  or NH could not be measured. Approximately 40% of the initially present hydrazine was converted to  $\text{NH}_3$ , and approximately half of it contributed to the formation of  $\text{N}_2\text{O}$ . All data were interpreted to favor a mechanism shown in

The addition of small amounts of UDMH (less than 1%) to hydrogen/air mixtures in a shock tube was found to decrease the delay periods usually observed after the passage of a shock front, whereas the addition of more than 3% UDMH increased the ignition delay [1261]. Apparently small UDMH concentrations release free radicals that trigger the  $\text{O}_2\text{-H}_2$  reaction.

## 4.5 Detonation of Hydrazine

The conditions under which the detonation of hydrazine liquid or vapor or foam may be initiated will be discussed under safety properties and detonability sensitivity in Section 8.4. The current section deals with mechanisms and kinetics that would enable the propagation of detonations, regardless of how they have been initiated.

### 4.5.1 Detonation of Hydrazine Vapor

The detonability of hydrazine vapor will be discussed again under safety properties in Section 8.4 of this chapter. The current section looks only at the kinetics of detonations in relation to thermal decomposition of hydrazine from an academic point of view.

The fundamental gas-dynamic characteristics of the detonation, instantaneous combustion (explosion) in constant volume, combustion at constant pressure, and deflagration for hydrazine, MMH, UDMH, SDMH, or trimethylhydrazine in mixtures with oxygen or air that are diluted with argon at varied initial pressure and temperature values were examined [1262, 1263]. Spray detonation is also potentially relevant to the study of pulse detonation engines (PDEs) and other hypersonic propulsion sys-

tems exploiting detonative reactions. The main parameters of these processes were analyzed both for the case of a gaseous propellant and for the case of a heterogeneous propellant where the propellant is a highly dispersed, sprayed aerosol cloud in an oxidant medium. Calculations were performed by means of the computer code SAFETY. Calculation results agreed with experimental data. For hydrazine by itself, detonation wave velocity was predicted to be  $D_0 = 2482$  m/s. For a stoichiometric mixture of gaseous hydrazine with oxygen the detonation wave velocity was predicted to be  $D_0 = 2595$  m/s. For a stoichiometric mixture of gaseous hydrazine with air the detonation wave velocity was predicted to be  $D_0 = 2003$  m/s. A poorly dispersed spray of liquid hydrazine aerosol in a stoichiometric proportion to oxygen was predicted to detonate at  $D_0 = 2534$  m/s.

An initial detailed kinetic model describing the hydrazine vapor detonation consisted of 33 reversible reactions and 13 species [1264]. A reduced kinetic model was then proposed using the principal component analysis of matrix F method as implemented in KINALC. It consisted of 26 reactions and 11 species. This model has been shown to be valid over a pressure range of 10 to 1010 kPa (0.1 to 10 atm). However, the predictions of the models were significantly affected by changes in the enthalpy of formation of  $N_2H_3$ , which was only known with poor accuracy. With the help of the full kinetic model, a value of  $A$ , the proportionality factor in the ZND model between the induction distance in the detonation wave and the detonation cell size, of  $27.5 \pm 3.0$  was derived considering that the collision efficiency of  $N_2H_4$  on the thermal decomposition of hydrazine is equal to that of  $N_2$ . The value of  $A$  for pure hydrazine detonation was shown to be strongly dependent on the value of the collision efficiency of  $N_2H_4$ . See also [1265].

#### 4.5.2 Detonation of Liquid Hydrazine

Despite numerous experiments testing the detonability of liquid, bubble-free hydrazine, it has not been possible to achieve detonation of liquid hydrazine. The propagation of induced shock waves in liquid hydrazine has been studied experimentally and modeled by computational methods, also in support of experiments measuring the effects of hypervelocity particle impacts on hydrazine tanks. The detonability of liquid hydrazine is discussed again under safety properties in Section 8.4 of this chapter.

The shock Hugoniot of liquid hydrazine was determined in a pressure range of 3.1 to 21.4 GPa (31 to 214 kbar) using an impedance matching technique [1266–1268]. Shock pressures were generated using a plane wave explosive driver system with different explosives and reference materials compared against the liquid hydrazine. The velocity of the shock wave in the liquid hydrazine and the free surface velocity of the reference materials were measured using different pin contact techniques. Shock velocities ranged from 3.72 to 6.76 km/s, depending on the type of donor charge and flat plate flyer. Plotting the shock wave velocity versus the surface wave velocity gave a linear function relationship. The experimental Hugoniot appeared smooth, and

there was no indication of a phase change. The shock Hugoniot of liquid hydrazine was compared against three other liquid Hugoniots – liquid ammonia, water, and carbon tetrachloride – and was closest to the Hugoniot for water and in between ammonia and carbon tetrachloride. The hydrazine Hugoniot was also compared to the “universal” Hugoniot for liquids. The universal Hugoniot for liquids is not a good approximation for the liquid hydrazine Hugoniot in the pressure range studied.

Several shock compression experiments have been conducted in an attempt to investigate the detonability of liquid hydrazine; however, the experimental results are not in agreement. Therefore, each experiment was reproduced numerically to evaluate in detail the shock wave profiles generated in the liquid hydrazine, including chemical kinetic experiments, chemical equilibrium calculations, and characterization of the EOS of liquid hydrazine [1269, 1270].

The parameters of shock-compressed liquid hydrazine were calculated within the framework of the approaches developed for studying shock compression of organic liquids and liquefied gases [1271–1274]. In the case when the mass velocities behind shock fronts do not exceed  $3.1 \text{ mm}/\mu\text{s}$ , it may be managed under an assumption of the retention of the unreacted, initial compound (hydrazine) behind a shock front. Detonation velocities of hydrazine solutions with such explosives as nitromethane and hydrazine nitrate correspond to the destruction of hydrazine to ammonia and nitrogen, which is accompanied by a noticeable energy release. The estimates demonstrated the possibility of detonation of liquid hydrazine at a velocity of  $8 \text{ mm}/\mu\text{s}$  with shock heating of the liquid to approximately 2000 K, which is comparable with the temperature observed behind a shock front during detonation of liquid explosives. Large values of the critical diameter of detonation (up to 1 m) are expected because of the large activation energy of hydrazine decomposition ( $223 \text{ kJ/mol} = 53.2 \text{ kcal/mol}$ ), which is almost 1.4 times larger than the activation energy of decomposition of standard explosives. In this case, their more rapid decomposition behind a shock front would result in a temperature increase that is enough for hydrazine destruction for peak times less than  $0.1 \mu\text{s}$ .

#### 4.6 Photolytic Decomposition of Hydrazine

Of the various methods for the study of hydrazine decomposition, the one initiated by photolysis is probably most easily accessible to analysis of the disappearance of hydrazine and the appearance of decomposition products. Photolytic studies of hydrazine decomposition are done for various reasons. One reason would be to study the mechanism of hydrazine decomposition with a method where the initiating energy is easily dosed (metered) and can be delivered in discrete pulses of preselected duration and intensity, such as in flash photolysis. Selective states just short of dissociation can be excited by coupling monochromatic radiation, typically provided by a laser, to absorptive vibrations of the molecule. This is a difference from thermal decompo-

sition, where the decomposing hot molecules occupy a broad band of energy states and only those at the high-energy end of the band have enough energy to dissociate. Photolysis is very suitable for selectively dissociating bonds in molecules by choosing monochromatic light and identifying the intermediates. The photolysis of hydrazine may occur in planetary atmospheres that are rich in ammonia and may be responsible for limiting the hydrazine yield in ammonia photolysis reactions studies as a means of making hydrazine. The environmental fate of hydrazine vapors inadvertently released into Earth's atmosphere depends on its rate of destruction by photolysis. The photolysis of hydrazine is undesirable if one wants to obtain UV spectra of hydrazine that are free from decomposition products.

#### 4.6.1 Photolysis of Hydrazine Vapor

The earliest studies on the photolytic decomposition of hydrazine vapor date back to 1929 [1275, 1276]. Hydrazine vapor in a 150-mL quartz vessel at 1.06 kPa (8 mm Hg) pressure and  $298 \pm 1$  K was illuminated with UV light from a mercury arc in a quartz bulb, and the total pressure increase was measured as a function of time. Selected gas samples were analyzed for gas composition. Hydrazine vapor absorbed UV light appreciably below 244 nm. The photolytic decomposition was found to lead to hydrogen and nitrogen as the main products, resulting in a tripling of the pressure in the flask. It was assumed that any hydrogen found must come from the secondary photolysis of ammonia, but no proof was offered for this hypothesis. The photochemical decomposition of ammonia proceeds at approximately one-tenth the speed of hydrazine decomposition. The data have been interpreted to indicate that the photolysis of hydrazine under these conditions is a chain reaction. The quantum efficiency was on the order of 13 molecules reacted per quantum of light absorbed.

One of the objectives of studies of the photolytic decomposition of hydrazine is to identify intermediate products of decomposition. In the case of photolysis as well as other modes of initiation, free radicals are presumed to play an important role. For a long time, the photolysis of hydrazine was believed to proceed through one or both of two mechanisms:

or

with nitrogen formation attributed to radical-radical reactions:

This hypothesis was temporarily contested by Stief and de Carlo [1153] as well as Kant and McMahon [1224] using  $^{15}\text{N}$ -isotope-labeled hydrazine. When a 50:50 mixture of  $^{14}\text{N}_2\text{H}_4$  and  $^{15}\text{N}_2\text{H}_4$  was irradiated,  $^{15}\text{N}_2$  and  $^{14}\text{N}_2$  were formed in approximately equal

proportions, whereas very little randomized  $^{14}\text{N}^{15}\text{N}$  could be observed [1153]. If the decomposition occurred by  $\bullet\text{N}_2\text{H}_3$  or  $\bullet\text{NH}_2$  free radicals, an approximately even statistical distribution of the isotopes should have occurred. An alternative explanation of the lack of randomization would be the disproportionation of  $\bullet\text{N}_2\text{H}_3$  radicals:

Depending on the (initially unknown) ratio of disproportionation to recombination for the  $\bullet\text{N}_2\text{H}_3$  radical, only 50% randomization could be expected via this mechanism. For the observed 13% randomization this ratio would have to be at least 2.8, which is very high in comparison to other free radicals. The authors concluded that, contrary to previous suggestions, the major portion of the dinitrogen in the photolysis of hydrazine formed by molecular elimination. However, a later, more detailed, study of the ratio of disproportionation of recombination of hydrazyl radicals showed that this number is indeed higher than 2.8, actually closer to 4.0 [1152]. Identifying randomization of isotopic nitrogen with the combination  $\text{N}_2\text{H}_3$  and non-randomization with the disproportionation of  $\text{N}_2\text{H}_3$ , the ratio of disproportionation to combination was approximately 4. This was an unexpectedly large value, being nearly 30 times larger than that for the analogous hydrocarbon radical  $\text{C}_2\text{H}_5$ . Hydrogen atoms generated by the photolysis of methyl mercaptan were used to abstract hydrogen from hydrazine and form hydrazyl radicals without thermal or photolytic excitation of hydrazine molecules.

Several alternative mechanisms were discussed. The combination of two hydrazyl radicals with the unknown tetrazane and splitting of terminal  $\text{NH}_2$  groups would explain only complete (100%) randomization because two different  $\bullet\text{N}_2\text{H}_3$  radicals are likely to combine:

Since the experimentally observed randomization is 50%, some other mechanism must be contributing. Based on studies of the oxidation of hydrazine in aqueous solution, decomposition of the tetrazane to triazene was proposed, which is at least as unstable as tetrazane [518, 1277]:

Stief assumed that this mechanism would come into play in the gas phase as well and that it accounted for the 50% randomization observed. Certainly, efforts have been made to identify the tetrazane and triazene intermediates postulated by these au-

thors [342]. Some of this work is discussed in the chapter “Hydronitrogens.” The experimentally determined disproportionation : combination ratio is  $4.0 \pm 0.6$  with certain experimental errors due to insufficient isotopic purity of the starting materials. To a certain extent, radical cross-disproportionation may further cloud the issue:

In the direct photolysis of hydrazine (as opposed to that using methyl mercaptan as “sensitizer”), the direct formation of hydrogen and nitrogen via

cannot be disregarded and may well contribute to the overall very complex mechanism. When studying the energy transfer from metastable, electronically excited  $\text{N}_2$ , Ar, Kr, Xe to hydrazine and isoelectronic organic molecules, it was an unexpected result to find that cleavage of the weak central bond is much less likely than that of the stronger terminal bonds [1278]. The threshold energies for dissociation channels by reaction with  $\text{N}_2^*$  are as follows (an asterisk \* denotes excited species):

The data for hydrazine were difficult to interpret because of the speed of secondary reactions. Time-resolved studies have shown that  $\bullet\text{NH}_2$  is not a primary product of photodissociation at 193 nm, consistent with the prevailing dominant reaction pathway [1279–1281]

The photolysis of hydrazines occurs inadvertently while trying to determine absorption spectra in the vacuum UV region. Photoionization thresholds of ammonia, hydrazine, MMH, and UDMH were measured in a molecular-beam apparatus [401, 402]. The ionization thresholds of hydrazines are very broad, as opposed to a sharp ionization threshold of ammonia at 10.16 eV. The measured photoionization threshold potentials are 8.32 eV for hydrazine, 8.05 eV for MMH, and 7.87 eV for UDMH.

The dependence of the relative  $\bullet\text{NH}_2$  yield on fluence (in a range of 0.1 to  $100 \text{ J cm}^{-2}$ ) of laser radiation from a  $\text{CO}_2$  laser and pressure of hydrazine vapor (from 1.4 to  $2.6 \text{ Pa} = 10^{-3}$  to  $0.02 \text{ mm Hg}$ ) was examined using the 935, 944, and  $953 \text{ cm}^{-1}$  laser lines [1282]. A photon at  $935 \text{ cm}^{-1}$  corresponds to an energy of 11.9 kJ/mol. The three initiating lines were in the vicinity of the  $937 \text{ cm}^{-1}$  absorption band of hydrazine, which is attributed to the anti-symmetric wagging mode. While shock-wave studies

point to ammonia as a co-dissociating intermediate and source of  $\bullet\text{NH}_2$ , it does not appear to be a major contributor here under conditions of “collisionless” multi-photon dissociation at pressures of low collision frequency, nor is the direct dissociation of hydrazine to nitrogen and hydrogen, which is very exothermic.

In addition to free radicals as energetic species, many of the molecular species leaving the hydrazine decomposition reaction are in an electronically excited state from which they may lase if a population inversion prevails. The production of species in electronically excited states was observed during the photolysis of  $\text{N}_2\text{H}_4$  or  $\text{N}_2\text{D}_4$  at 193 nm [1283]. The visible spectrum in the region 420–900 nm showed a broad and largely unstructured continuum emission upon which was superimposed a large number of well-resolved spectral features corresponding to  $\text{NH}_2(\text{A})$  or  $\text{ND}_2(\text{A})$ . The population of the excited states may depend on the initial temperature of the hydrazine vapor. This was demonstrated by photolyzing hydrazine vapor at 573 K in comparison to hydrazine vapor at 296 K and the cross sections for  $\text{NH}_3$ ,  $\text{N}_2\text{H}_4$ ,  $\text{NH}(\text{A}^3\Pi)$ , and  $\text{NH}_2(\text{A}^2\text{A}_1)$  were determined at the same time [1284]. See also [433, 434].

#### 4.6.2 Effect of Wavelength of Incident Light

The ratio of amino to hydrazyl radicals formed in the photolysis of hydrazine changes with the wavelength of the incident radiation. It has been suggested [1281] that at  $\lambda > 200$  nm cleavage to amino radicals

occurs preferentially, whereas at  $\lambda < 200$  nm hydrazyl radicals are formed first (which is  $\text{N}_2\text{H}_4 \rightarrow \bullet\text{N}_2\text{H}_3 + \text{H}\bullet$ ):

At 200 nm  $\text{N}_2\text{H}_4 \rightarrow 2\bullet\text{NH}_2$  slightly predominated, with 55% of all hydrazine decomposing via this route [1281]. On the other hand, at 105 nm,  $\text{N}_2\text{H}_4 \rightarrow \bullet\text{N}_2\text{H}_3 + \text{H}\bullet$  was found to predominate [1285]. At 123.6 and 147 nm  $\text{N}_2\text{H}_4 \rightarrow \bullet\text{N}_2\text{H}_3 + \text{H}\bullet$  was shown to be present because only that reaction can be inhibited by deuterioethylene  $\text{C}_2\text{D}_4$  addition [1286].

Monochromatic 199-nm radiation from a condensed aluminum spark passed through a monochromator was used to study the quantum yield of the photochemical decomposition of gaseous hydrazine, but the researchers' findings disagreed with those of Elgin and Taylor, possibly as a result of analysis errors in decomposition product composition [1287]. In the low-pressure range at 265 Pa (2 mm Hg), the quantum yield was 1 and increased to 1.7 at 1866 Pa (14 mm Hg). The composition of the reaction products was dependent on the initial hydrazine pressure. More hydrogen was formed at the low hydrazine pressures than at higher pressures.

When pure hydrazine was photolyzed with krypton resonance lines (123.6 and 116.5 nm), an emission was observed at 336 nm that was attributed to the  $\text{NH}$  radi-

cal [1286, 1288]. Except for some  $\cdot\text{OH}$  due to water present in the hydrazine, no other emissions were noted initially between 200 and 700 nm. Only after several minutes was ammonia emission at 324 nm detected. The 336-nm emission can be used as an indicator of the NH concentration in the reaction mixture. The NH concentration (336-nm intensity) decreased with time, whereas the 324-nm emission (presumed to belong to ammonia) increased with time. No emissions were observed when the xenon resonance line at 147 nm was used in the hydrazine photolysis.

The absorption coefficients of ammonia and hydrazine at four different wavelengths (116.5, 123.6, 129.5, and 147 nm) and emission spectra due to  $\text{NH}^*$  were measured in the vacuum UV range [1289]. Xenon and krypton emission lines were used to initiate the photolysis of hydrazine at pressures close to 26.6 Pa (0.2 mm Hg) in both static and flow systems. In the flow system, only the  $\text{NH}^*(^3\Pi \rightarrow ^3\Sigma)$  band was observed, whereas in the static system a  $\text{NH}(^1\Pi \rightarrow \Delta)$  began to appear after a short time of illumination, which must be due to the ammonia formed in the hydrazine decomposition.

Continuous photolysis was achieved with the 206.2-nm resonance line from an iodine lamp [1290, 1291]. The hydrazine partial pressure was 266–1063 Pa (2–8 mm Hg) in xenon gas at up to 36 kPa (270 mm Hg). The inert heavy gas helped to maintain isothermal conditions during the photolysis reactions. For flash photolysis, a flash of 5000 J was discharged within 5  $\mu\text{s}$  into hydrazine vapor that was contained in a cell 56 mm in diameter and 1 m in length. For isothermal reaction conditions, inert gas was again added to the hydrazine vapor, this time argon at a ratio of 100 : 1.2. Approximately 5% of all the hydrazine was decomposed after a single flash discharge under isothermal conditions. Time-resolved spectra of the photolysis products showed:

- (1) The well-known absorption spectrum of  $\text{NH}_2$  radicals that lasted for several hundred microseconds
- (2) NH radicals at 336 nm that lasted for approximately 18  $\mu\text{s}$
- (3) Continuous absorption across the entire UV range, lasting for only around 10  $\mu\text{s}$ , which was attributed to the  $\cdot\text{N}_2\text{H}_3$  radical
- (4) Ammonia formation beginning after 50  $\mu\text{s}$

The formation of amino radicals is assumed to be a secondary effect of photolysis:

Lasers offer the opportunity to study the effect of wavelength on the photolysis of hydrazine with very high accuracy as to the energy of the incident radiation. An argon fluoride excimer laser emitting at 193 nm was used to study the photolysis of hydrazine [1279, 1280]. A secondary tunable dye laser scanned through a range near  $18400\text{ cm}^{-1}$  as a diagnostic tool. Amino radical fluorescence was observed at 597 and 571 nm. The dependence of laser-induced fluorescence due to  $\cdot\text{NH}_2$  on the initial hydrazine pressure was linear from 0 to 107 Pa (0 to 800  $\mu\text{m Hg}$ ). Amino radicals are not a major primary product of the laser photolysis of hydrazine. The intensity of visible fluorescence emission at 450–600 nm was linearly proportional to the initiating laser energy

from 0 to 8 mJ/pulse. Strong two-photon absorption from  $\text{NH}(\text{A}^3\Pi)$  was also observed and attributed to secondary absorption by the  $\bullet\text{N}_2\text{H}_3$  primary photoproduct. While some authors favored the secondary photolysis of  $\text{N}_2\text{H}_3$  and the mechanism for the excitation of  $\text{NH}$ , other investigators suspected that another intermediate might be involved. In later studies, also with an argon excimer laser at 193 nm, the photolysis of hydrazine resulted in triplet emission of  $\text{NH}$  imidogen [1292, 1293]. Similar observations had been made earlier with the same laser aimed at ammonia, hydrogen azide, hydrazine hydrate, or methylamine. Relatively strong emission was observed from the first rotational level of  $\text{NH}(\text{A}^3\Pi)$ . Of all the molecules tested, the largest relative population of the first vibrational state ( $v = 1$ ) was found with hydrazine. In the rotationally resolved spectrum, emissions from rotational levels up to  $N' = 28$  were observed. The fluorescence intensity of the  $\text{NH}(\text{A}^3\Pi \rightarrow \text{X}^3\Sigma)$  emission was found to depend on the 1.8<sup>th</sup> power of the laser intensity, suggesting that absorption of at least two photons is required to generate an excited  $\text{NH}^*$  species.

#### 4.6.3 Flash Photolysis of Hydrazine Vapor

The flash photolysis of hydrazine was also studied as part of the investigation of the explosive oxidation of ammonia and hydrazine [521]. The composition of the decomposition products varied with the flash intensity. Assuming two overall reactions

and

it was found that with a flash energy of 1150 J, 75% of the hydrazine was decomposed and the ratio (1):(2) was 54:46. The possibility of secondary thermal or photolytic ammonia dissociation was ruled out because ammonia added to the system was not thermally decomposed. The differences in the final product analysis were attributed to the varying stability of the  $\bullet\text{N}_2\text{H}_3$  radical at different temperatures. These results agreed with Ramsay's interpretation of hydrazine photolysis [1225, 1294] based on the absorption of hydrazine in its photolysis.

A re-investigation of the flash photolysis of hydrazine in an excess of inert gas revealed a new absorption band of the  $\text{NH}$  radical and a previously unknown continuous absorption below 400 nm that has been attributed to the  $\bullet\text{N}_2\text{H}_3$  radical [1295]. Dilution by a large amount of inert gas served to maintain isothermal conditions during the reaction. The experimenters used a flash of shorter duration ( $t_{1/2}$  approximately 5  $\mu\text{s}$ ) than those used by previous investigators. An optical path of up to 16 m was achieved by multiple reflection of the analyzing beam in a cylindrical cell with a diameter of 55 mm.  $\text{NH}$  absorption was measured at 336 nm ( $\text{A}^3\Pi \rightarrow \text{X}^3\Sigma$  with a half-life of 18  $\mu\text{s}$ ), and  $\text{NH}_2$  absorption was measured at 597.6 nm.  $\text{NH}_2$  absorption was visible for several hundred microseconds.

In view of results obtained during the photolysis of hydrazine at 2062 Å in the presence of ethylene [1296], it has been postulated that of the four possible photolytic reactions

the reaction  $\text{N}_2\text{H}_4 \rightarrow \text{N}_2 + 2\text{H}_2$  does not provide the main contribution, as was originally assumed. Instead, the reaction

is the main initial step in the photolysis of hydrazine. The improved experimental techniques were now used to investigate the origin of  $\text{NH}_2$  in the isothermal flash photolysis of hydrazine following the formation and decay of this radical, as evidenced by its absorption in the 597.6-nm band [1295]. It is unlikely that  $\text{NH}$  forms by the reaction

because  $\text{NH}$  disappears with a half-life time of 18  $\mu\text{s}$ , whereas  $\bullet\text{NH}_2$  sticks around much longer. Between 0 and 250  $\mu\text{s}$  the rate of disappearance of  $\bullet\text{NH}_2$  in photolyzed hydrazine was much slower than in photolyzed ammonia, despite the initially higher  $\bullet\text{NH}_2$  concentration in hydrazine. Ammonia, whose photolysis has already been exhaustively investigated, was also used in this study in some flash photolytic experiments in the same setup as a baseline for comparison. Based on these flash photolysis experiments, the authors concluded that  $\bullet\text{NH}_2$  plays only a minor role in the photolysis of hydrazine [1295]. Amino  $\bullet\text{NH}_2$  radicals play an important role in the attempted preparation of hydrazine by the photolysis of ammonia, possibly also occurring in the atmospheres of planets with ammonia atmospheres, and in the photolytic decomposition of hydrazine. The rates of recombination of amino radicals for bimolecular and trimolecular reactions are summarized in Table 56. The rate of disappearance of the  $\text{NH}_2$  radicals is immediately tied to the rate of formation of hydrazine.

The rate of amino radical disappearance is proportional to the square of the amino radical concentration:

$$\frac{d[\text{NH}_2]}{dt} = 2k_1[\text{NH}_2]^2$$

When studying the effect of pressure on  $k_1$ , it was noted that the reaction proceeds by “self-exciting collisions” [1299]. The decay profile of  $\bullet\text{NH}_2$  radicals at 598 nm,  $\text{NH}$  radicals at 336 nm, and yet unidentified species (believed to be  $\text{N}_2\text{H}_3$  radicals) at 290 nm has been measured for up to 300  $\mu\text{s}$  after the initial photolysis flash. Attempts were

**Table 56:** Reaction rates for recombination of amino radicals.

| Rate expression                                                      | Temperature, K | Pressure, mm Hg | Diluent         | Reaction type |
|----------------------------------------------------------------------|----------------|-----------------|-----------------|---------------|
| $(1.00 \pm 0.50)e^{18} \text{ cm}^6 \text{ mol}^{-1} \text{ s}^{-1}$ | 300–500        | 0–20            | Ar              | termolecular  |
| $(1.00 \pm 0.50)e^{19} \text{ cm}^6 \text{ mol}^{-1} \text{ s}^{-1}$ | 300–500        | 0–20            | NH <sub>3</sub> | termolecular  |
| $(1.50 \pm 0.75)e^{13} \text{ cm}^3 \text{ mol}^{-1} \text{ s}^{-1}$ | 300–500        | 1000            | N <sub>2</sub>  | bimolecular   |
| $6.19e^{13} \text{ cm}^3 \text{ mol}^{-1} \text{ s}^{-1}$            | 298            | 250–1520        | NH <sub>3</sub> | bimolecular   |

Data source: [1297, 1298]

made to check the validity of Beer's law for the 597.6-nm band of the  $\bullet\text{NH}_2$  radical by plotting the optical density as a function of optical pathlength. The law is not fulfilled, and a straight line could not be obtained. This is probably because more than one line or band contributes to the absorption at this wavelength. This had already been observed by other authors [1298]. The unexplained continuum at 290 nm showed some correlation with the concentration of NH radicals. If the continuum is due to  $\bullet\text{N}_2\text{H}_3$ , then secondary photolysis of  $\bullet\text{N}_2\text{H}_3$  could form some NH:

This reaction and hydrogenolysis

are secondary sources for NH<sub>2</sub> in the hydrazine photolysis, but  $\text{N}_2\text{H}_4 \rightarrow \bullet\text{NH}_2 + \bullet\text{NH}_2$  has now been eliminated as a possible source. This conclusion is also supported by the observation that NH<sub>2</sub> concentration reached its maximum only several microseconds after the flash, at a time when the continuum (possibly N<sub>2</sub>H<sub>3</sub>) was already decaying.

A similar study on the flash photolysis and photolysis with continued irradiation of hydrazine, both under adiabatic and isothermal conditions, led to the conclusion that at 200 nm the primary step is the hydrogen abstraction leading to hydrazyl radicals [1291]:

Laser flash photolysis of hydrazine vapor at 296 K from a 248.3-nm laser resulted in the formation of H atoms, which were directly measured using a continuous-wave-resonance fluorescence detection of H(<sup>2</sup>S) technique at 121.6 nm. Other species were studied by their absorption at 253.65 nm [1300]. Initially, the primary quantum yield of H formation was reported as  $0.85 \pm 0.15$  or near unity when tested at additional wavelengths of 193, 222, and 248 nm. By repeating the primary reaction of H atoms with hydrazine at various temperatures between 222 and 296 K, it was possible to determine the Arrhenius rate equation (and the activation energy) of this reaction to be  $k_1 = (7.57 \pm 1.55) \times 10^{-12} \exp(-1150 \pm 50/T) \text{ cm}^3 \text{ mol}^{-1} \text{ s}^{-1}$ . This was consistent with a metathetical reaction in which the reaction proceeds via H-atom abstraction in hydrazine to give H<sub>2</sub> and N<sub>2</sub>H<sub>3</sub> as the major products. Later tests gave the quantum yield

at 193 nm as  $1.01 \pm 0.12$  and at 222 nm as  $1.06 \pm 0.16$  [1301]. The high yield of H atoms observed in the photolysis was consistent with the continuous UV absorption spectrum of hydrazine. A second-order rate constant of hydrogen abstraction from hydrazine by atomic hydrogen was determined from a series of experiments with varying hydrazine concentrations in helium. From these tests, the rate equation was derived as  $k_1 = (11.7 \pm 0.7) \times 10^{-12} \exp(-1260 \pm 20/T) \text{ cm}^3 \text{ mol}^{-1} \text{ s}^{-1}$ , somewhat different from the older equation published earlier [1302]. Whereas only 5% of the hydrazine was destroyed under isothermal conditions, each flash discharge destroyed more than 80% of the hydrazine under adiabatic conditions at 106–930 Pa (0.8–7 mm Hg). The stoichiometry under these conditions was

#### 4.6.4 Photolysis in the Presence of Additives

Sometimes short-lived intermediate species can be trapped or a key mechanism can be inhibited by conducting the photolysis of hydrazine in the presence of additives. Nitric oxide [1227, 1303, 1304], ethylene  $\text{C}_2\text{H}_4$  [1296], deuterioethylene  $\text{C}_2\text{D}_4$  [1286], and propylene [1303] have been used as additives and radical scavengers. Other additives generate additional free radicals and initiate additional chain reactions. Methyl mercaptan was already mentioned. Dimethyl mercury has been used for the same purpose.

The addition of hydrogen, nitrogen, or ammonia to the hydrazine did not affect its rate of photolytic decomposition [1275, 1276]. When the hydrazine vapor was sensitized with mercury vapor and then irradiated with light from a mercury lamp, hydrazine decomposition occurred much more rapidly than under any other condition tested. The photosensitized decomposition of hydrazine was 40 times faster than that of ammonia under identical conditions. The rate of the sensitized decomposition was directly proportional to the incident light intensity.

Photolysis in the presence of water vapor would be dominated by the interaction of hydroxyl radicals with hydrazine. Hydroxyl radicals are a strong oxidizing agent and will destroy hydrazine. This reaction is believed to be responsible for the destruction of hydrazine or MMH vapor in the troposphere [1305] (Section 10.4.3). The photolysis of aqueous hydrazine solutions will produce some dihydrogen gas [1306, 1307], whereas none is produced during slow liquid-phase decomposition of hydrazine solutions.

**Effect of Radical Scavengers.** When hydrazine/ethylene mixtures are photolyzed, ethylene will scavenge hydrogen atoms and compete with reaction (10) in Figure 38 [1296]. Accordingly, the hydrogen yield decreases with increasing ethylene pressure:

At the wavelength at which this experiment was conducted (206.2 nm), ethylene is transparent and will not become electronically excited. Ethylene pressures of 20–

11400 Pa (0.15–86 mm Hg) were used, whereas the hydrazine pressure was kept constant at 1.2 kPa (9.3 mm Hg). The quantum yield for  $\text{H}_2$  formation dropped from 1.2 without ethylene to 0.1 for an ethylene : hydrazine molar ratio of 8 [1296]. A similar effect was observed when using deuterated ethylene  $\text{C}_2\text{D}_4$  instead of  $\text{C}_2\text{H}_4$  [1286]: the quantum yield of hydrogen by photolysis at 147 nm and 66 Pa (0.5 mm Hg) dropped from 0.72 to 0.55 at a hydrazine : deuterioethylene ratio of 5. Perhaps the  $\text{C}_2\text{D}_4$  test should be repeated at higher scavenger : hydrazine ratios (up to 8) like those used with  $\text{C}_2\text{H}_4$ . The quantum yield of nitrogen in this experiment remained unchanged (0.5). The remaining hydrogen formed in this test was attributed to reactions not involving hydrogen radicals, such as the direct molecular elimination of hydrogen

or decomposition of diazene

The latter reaction was initially thought to be very likely because, in the presence of  $\text{C}_2\text{D}_4$ , the quantum yields for  $\text{H}_2$  and  $\text{N}_2$  are equal. However, later studies by the same authors [1227, 1304] with the addition of NO instead of  $\text{C}_2\text{D}_4$  reversed this conclusion.

In the same way that ethylene acts as a selective scavenger for hydrogen atoms, nitric oxide acts as a scavenger for amino and hydrazyl radicals [1303]:

If  $^{15}\text{N}_2\text{H}_4$  is used for the  $^{14}\text{NO}$ -inhibition study, the nitrogen formed in the preceding reaction will have a molecular weight of 29 [1227, 1304]:

As was discussed in earlier sections on the thermal and photolytic decomposition of mixtures of  $^{14}\text{N}_2\text{H}_4$  and  $^{15}\text{N}_2\text{H}_4$ , the lack of randomization of nitrogen indicated a molecular elimination of nitrogen with only a minimum of radical disproportionation. The formation of  $^{15}\text{N}_2$  in the presence of  $^{14}\text{NO}$  is then attributed to the direct molecular process. Complete scavenging of  $^{15}\text{N}\bullet\text{H}_2$  and  $^{15}\text{N}_2\text{H}_3\bullet$  radicals must be achieved by adding enough  $^{14}\text{NO}$  to suppress all radical disproportionation. One objective of the investigation was to determine how much NO was required to achieve a complete suppression of chain reactions.

The effect of NO addition on the rate of decomposition product formation is expressed as a percent of the rate observed with  $^{15}\text{N}_2\text{H}_4$  alone without NO addition. The  $^{15}\text{N}_2\text{H}_4$  partial pressure was 66 Pa (0.5 mm Hg), and 147 nm UV light was used for photolysis. The addition of 5–50% NO reduced the rate of  $^{15}\text{N}_2$  formation drastically to 25% of its value in the absence of NO. It was found that 5% NO was enough to bring about this effect, and the rate of  $^{15}\text{N}_2$  formation did not change between 5 and 50% NO. The

addition of  $^{14}\text{NO}$  also led to the formation of  $^{14}\text{N}^{15}\text{N}$ . Its rate of formation increased to 25% of that for  $^{15}\text{N}_2$  in the photolysis of hydrazine alone with the first 5% NO addition. Its rate remained constant at 5–50% NO. These two results indicated that 5–10% NO was enough to scavenge all amino radicals via the reaction

Substantial amounts of  $^{14}\text{N}_2$  were also formed in the photolysis. For instance,  $^{14}\text{N}_2$  did not show up until 5%  $^{14}\text{NO}$  addition was exceeded and increased linearly with the NO concentration. The delay in the formation of  $^{14}\text{N}_2$  is explained by the fact that  $^{14}\text{NO}$  reacts preferentially with  $^{15}\text{NH}_2$ , and only after all amino and hydrazyl radicals are scavenged is NO available to enter into other reactions, presumably a chain reaction involving hydrogen atoms and hyponitrous acid:

However, as the previous tests with  $\text{C}_2\text{D}_4$  had shown, the supply of hydrogen atoms is insufficient to explain the large amount of  $^{14}\text{N}_2$  formed unless a chain reaction constitutes part of the mechanism. A delayed increase in the rate of  $^{14}\text{N}_2$  formation was also observed in the photolysis of ammonia in the presence of NO. Since no  $^\bullet\text{N}_2\text{H}_3$  radicals are formed in this system, the preferential interaction of NO with  $^\bullet\text{NH}_2$  is given further credence.

It has been shown that the addition of NO decreased the  $^{15}\text{N}_2$  formation to 25% of its original value. This 25% was evidently formed by direct molecular elimination, whereas the remaining 75% was formed by radical disproportionation. The hydrogen:nitrogen ratio gave further evidence of the mechanism by which this molecular elimination occurred. Whereas, based on preliminary results with  $\text{C}_2\text{D}_4$ , it was previously assumed to occur via

with an  $\text{H}_2:\text{N}_2$  ratio of 1, the later measurement of an  $\text{H}_2:^{15}\text{N}_2$  ratio of 2.3 made a direct split of the hydrazine molecule to diazene more likely:

The NO inhibition tests also allow a statement on the ratio of disproportionation:combination of radicals. The uncertainty regarding this ratio had previously

made it difficult to interpret the results of mixed  $^{15}\text{N}_2\text{H}_2$ — $^{14}\text{N}_2\text{H}_4$  tests. The disproportionation of  $\text{N}_2\text{H}_3$

or cross-disproportionation of  $\bullet\text{NH}_2$  and  $\bullet\text{N}_2\text{H}_3$

results in the production of non-randomized  $^{15}\text{N}_2$  (the disappeared 75%). The randomized nitrogen (see [1153]) resulted from the combination of radicals. The ratio of disproportionation to combination was now found to be 5, in good agreement with a ratio of 4 previously deduced from other measurements [1286].

Some early investigators had reported the formation of hydrogen peroxide during the decomposition of hydrazine in the presence of water. Although this could not be confirmed by later investigators, it was of interest to investigate the photolysis of hydrazine (hydrazinium ion) in the presence of added hydrogen peroxide and vice versa [1308]. Free hydroxyl radicals formed by the photolysis of  $\text{H}_2\text{O}_2$  above 220 nm are hypothesized to attack hydrazinium(1+) ions as follows, but experimental proof is lacking:

Of course, hydrogen peroxide reacts with hydrazine (at higher pH) also without stimulation by photolysis and sometimes hydrogen peroxide forms as an intermediate in the autoxidation and radiolysis of hydrazine solutions.

#### 4.6.5 Initiation of Explosive Decomposition by Flash Photolysis

Whereas kinetic and photolysis experiments are usually conducted with very low and, hence, safe partial pressures of hydrazine, another way to study the photolysis of hydrazine is to operate at the brink of explosive vapor concentrations. Only minimal decomposition occurs in the vapor during the pre-irradiation period. However, the energy added by a flash of exactly timed duration is sufficient to make the vapor explode. This mode of hydrazine decomposition has been thoroughly investigated [1309–1311]. This work is unique because it studied the time-dependent phenomena that led to the explosion of hydrazine vapor when irradiated with a flash, rather than trying to solve the problem with quasi-steady explosion theory, which was found to be of little use in this case. Employing a kinetic scheme, some reaction paths resulting from the UV flash irradiation of initially quasi-steady samples of hydrazine were formulated. Calcula-

tions showed that under certain conditions (100%  $\text{N}_2\text{H}_4$  at  $1.7 \times 10^{-3} \text{ g/cm}^3$  and 400 K, 6-cm pathlength,  $\lambda = 225 \text{ nm}$ ) flash durations below  $300 \mu\text{s}$  will not initiate an explosive instability, whereas longer flashes will input sufficient activation energy to initiate an explosion. Similar calculations were also performed for MMH and UDMH [1311]. The results were also compared to those obtained with ozone, which decomposes more readily than any of the hydrazines. For identical initial conditions, the half-life of hydrazine was the longest, 295 vs.  $184 \mu\text{s}$  for MMH or  $148 \mu\text{s}$  for UDMH. The dissociation energy for the photodissociative step of hydrazine

was assumed to be  $240 \text{ kJ/mol}$  ( $57.1 \text{ kcal/mol}$ ). Five selected cases were assumed to be typical borderline cases, and differential equations were established to determine whether photolysis would lead to explosion:

1. The optically thin sample is subjected to an arbitrarily short, intense UV pulse.
2. The optically thin sample is subjected to constant, steady-state UV flux.
3. The optically thin sample is subjected to a non-steady-state UV flux that ultimately becomes steady.
4. The optically thick sample is subjected to an arbitrarily short, intense UV pulse.
5. The optically thick sample is subjected to a steady-state UV flux.

The explosive decomposition of hydrazine is characterized by free-radical chain processes in which the variety of different chemical substances appears more significant than the details of the energetics of their reactions. Very rapid data acquisition with spectrometers is required to resolve the concentration-time profile of reacting species in the photolytic initiation of hydrazine or ozone explosive decomposition. Low sample pressures and long absorption paths make it possible to sample every millisecond, fast enough to be comparable to the mean time between intermolecular collisions. The spectra of at least four different substances were observed during the photolysis of hydrazine and photolytically initiated explosions [1312]. In this study,  $\text{NH}_2$  was characterized by a system of lines in the 400- to 600-nm region,  $\text{NH}$  by lines in the vicinity of 300 nm. A weak continuum around 300 nm is associated with hydrazine. A transient, diffused spectrum was observed in the 600-nm region and was tentatively attributed to the hydrazyl radical  $^\bullet\text{N}_2\text{H}_3$ .

#### 4.6.6 Other Photolytic Reactions

Hydrazine photolysis takes place as a yield-limiting step in the photolysis of ammonia that was intended as a method for making hydrazine. If hydrazine forms by the photolysis of ammonia in the atmosphere of Jupiter, its equilibrium concentration will be limited by the photolytic decomposition of hydrazine. Study of the photolysis of ammonia at 184.9 nm revealed that the extinction coefficient of hydrazine is at least six times as large as that of ammonia at the same wavelength [1313, 1314]. Any energy ra-

diated into the system would thus be preferentially absorbed by hydrazine and lead to its decomposition, unless a large excess of ammonia is maintained. A hydronitrogen compound that decomposes even more readily than hydrazine and whose photolysis has also been thoroughly investigated is hydrogen azide,  $\text{HN}_3$ . Some of the intermediate species involved are the same for both hydrazine and hydrogen azide. Some of the experimental techniques described in these references may be useful for the study of the photolysis of hydrazine as well.

#### 4.7 Radiolytic Decomposition of Hydrazine

The decomposition of hydrazine by radiation is of practical interest because it limits the yield during various hydrazine synthesis processes through radiolysis of ammonia. Also, for hydrazine applications in outer space, exposure to cosmic radiation or even intense radiation as in the van Allen belt may result in an increased rate of decomposition and pressure buildup in hydrazine propellant tanks. Hydrazine as a boiler feedwater additive in nuclear power plant primary steam circuits is subjected to a wide array of radiation, mostly neutron radiation and  $\gamma$  radiation, but possibly also including  $\beta$  radiation. Any one of these radiations will decompose hydrazine.

On long-term deep-space missions, radioisotope thermoelectric generators (RTGs) provide electric power from the heat generated by the decomposition of radioactive isotopes. Although RTGs are shielded and placed on extendable booms away from the spacecraft core, some radiation penetrates the shielding. Propellant tanks close to the RTGs are still exposed to nuclear radiation. Because oxidizers are less sensitive to radiation damage than fuels, it would be best to design spacecraft such that the oxidizer tank is between the radiation source and the fuel tank, serving as a radiation shield. Hydrazine radiolysis in a high-radiation environment may cause the propellant tank pressure to increase [1315, 1316].

##### 4.7.1 Decomposition of Hydrazine by X-Ray Radiation

X-rays act in many ways like  $\gamma$  radiation, even though they constitute the “soft” low-energetic range of  $\gamma$  radiation. As long as the energy is high enough to penetrate structural materials, cosmic X-rays may also contribute to the decomposition of hydrazine propellant being stored in spacecraft. In a NASA study, hydrazine vapor at 2 kPa (15 mmHg) was irradiated with X-rays from a 250-kV source at 90–100  $\text{rad}^1/\text{min}$  [1317]. A total dose of 590 krad resulted in approximately 3% decomposition. Hydrogen, nitrogen, and ammonia were found in the decomposition products. A similar test with ammonia resulted in traces of hydrazine being formed

---

<sup>1</sup> rad = radiation dose absorbed, 1 rad = 0.01 J/kg; 1 R = 1 roentgen = 0.0002 Coulomb/kg

from ammonia. In a continuation of this work both hydrazine and 1,1-dimethylhydrazine were investigated [1318]. Higher dose rates (100–1000 rad/min.) and higher total absorbed doses (up to 2.3 Mrad = 23 kJ/kg) were used in this later study. The total dose of X-rays was selected to be equivalent to that potentially received through 0.38 mm (0.015 in.) of stainless steel for 2 years at 0.6–1.0 astronomical units from the Sun. Hydrazine vapor at 1.79 kPa (13.5 mm Hg) decomposed faster than UDMH (vapor or liquid) or hydrazine liquid, whereas hydrazine liquid decomposed at the slowest rate of all propellants and physical states examined in this series of tests. The primary radiolysis products from hydrazine were again nitrogen, hydrogen, and ammonia, but also traces of unidentified less volatile products were observed by GC. Although ground experiments have shown the effect of radiation on hydrazine decomposition, there are no reports from actual space missions where cosmic radiation contributed to an excessively fast rate of pressure buildup in hydrazine tanks. Usually other materials' incompatibility problems overshadow the effect of cosmic radiation. The  $G$  value for the decomposition of hydrazine vapor was proportional to the vapor density and (surprisingly) the 1.9<sup>th</sup> power of the glass surface per weight of vapor. In other reactions, the presence of surface quenched chain reactions. For liquid hydrazine, the surface area per unit weight entered only as approximately the 0.6<sup>th</sup> power. The extent of decomposition of the liquids was directly proportional to the total radiation dose and was independent of the dose rate. In hydrazine, decomposition stopped immediately with the discontinuation of irradiation.

#### 4.7.2 Hydrazine Decomposition by $\alpha$ , $\beta$ , and $\gamma$ Radiation

Long-term storage of hydrazine propellants in spacecraft subjects the propellant tanks to cosmic radiation. Some of the radiation may be energetic enough that it penetrates the tank walls. Cosmic radiation is energetic enough to penetrate propellant tank walls, which are usually made of titanium/aluminum alloys, which are a poor radiation shield. Irradiation experiments have been conducted to simulate this unusual storage condition. The results of hydrazine radiolysis depend on the energy content of the radiation, the radiation intensity, the hydrazine concentration, and the medium in which the reaction is carried out. They also depend on the physical state of the hydrazine to be irradiated. Hydrazine has been irradiated in the solid, liquid, dissolved, and gaseous states.

The decomposition of  $\text{N}_2\text{H}_4$  is accelerated by ionizing radiation such as electrons, protons, neutrons, or gamma radiation, most of which are found in cosmic radiation [1319, 1320]. The transient spectrum that can be observed on nanosecond pulse radiolysis of liquid anhydrous hydrazine showed a broad absorption band from 500 to 1000 nm, which has been attributed to solvated electrons.

During the radiolysis of polar amines and hydrazine, solvated electrons disappear by recombination with cations in the solvent. In hydrazine, solvated electrons disappear by reaction with the  $\text{N}_2\text{H}_3$  radical. There is a very low probability of survival of

more energetic electrons in solvents for which the efficiency of electron-radical recombination is low [1321–1323]. The recombination rate constant for recombination of the solvated electron with hydrazinium ions was  $(5 \pm 3) \times 10^7 \text{ mol}^{-1} \text{ s}^{-1}$  and was not diffusion controlled. The electron yield can be determined by scavenging with biphenyl, and for nanosecond pulses it was on the order of  $G = 3.4$ . The extinction coefficient of solvated electrons in hydrazine at 1000 nm is  $18500 \text{ mol}^{-1} \text{ cm}^{-1}$ . Irradiated hydrazine also has a small absorption band in the UV range that is like the one observed in irradiated ammonia [1324]. To study reactions between hydrazine and solvated free electrons, therefore, hydrazine has been introduced into deeply colored solutions of alkali metals in liquid ammonia [1325, 1326]. The reaction between hydrazine and ammoniated electrons was followed by absorption measurements, and it was shown that it is not a simple single-step reaction but a two-step reaction in which hydrazine acts as a weak acid in ammonia:

From these kinetic measurements, the pK of hydrazine in ammonia was calculated as pK = 13. This agreed quite well with earlier potentiometric measurements at 213 K. The radiolysis of hydrazine in ammonia forms azide ions. By measuring the  $G$  values for the disappearance of hydrazine in relation to those for the formation of nitrogen and azide, it was noted that the sum of the three  $G$  values is not constant. The following mechanism by way of imide and diazene was proposed to explain the azide formation:

The recombination rate constant of solvated electrons with acidic ions  $\text{N}_2\text{H}_5^+$  is  $(5 \pm 3) \times 10^7 \text{ mol}^{-1} \text{ s}^{-1}$ , and the reaction is not diffusion controlled.

Samples of 2.8, 7, and 10 mL anhydrous hydrazine were vacuum degassed and loaded into 14-mL metal bomblets under argon for radiolysis tests in a  $^{60}\text{Co}$  source [1327–1329]. Bomblets were made from Ti-6Al-4V alloy. At a dose rate of  $6 \times 10^5 \text{ rad/h}$ , 1.6% of the hydrazine was decomposed after 118 h, as indicated by a pressure rise to 303 kPa absolute (44 psia). The rate of gas formation was approximately 0.1 mL gas STP  $\text{Mrad}^{-1} \text{ g}^{-1}$ . Low-dose-rate experiments at 5600 rad/h for 189 d for a total dose of 24.9 Mrad indicated  $G$  values of 7.7, much higher than in the high-dose-rate experiments. The pressure increase in a control bomblet without irradiation was only 10% of that in the irradiated sample. In subsequent experiments, bomblets made of CRES-347, Al-1100, and Al-6061 were tested in addition to those made of Ti-6Al-4V. A series of experiments was conducted for irradiating anhydrous hydrazine in Ti-6Al-4V vessels filled as described previously. All radiation exposures were at 295 K (22°C) and a dose rate of  $6.16 \times 10 \text{ rad/h}$ . Several different sample volumes were used so that the

liquid-vapor ratio was varied. Hydrazine vapor was the only gas present over the liquid during irradiation. The range of volumes of liquid samples was 3–10 mL, which corresponds to 20 to 66% of the total vessel volume. The results showed that the formation of gaseous products not condensable at 195 K (–78.5 °C), i.e.,  $N_2$  and  $H_2$ , was unaffected by a change in ullage. In addition to anhydrous hydrazine, a fuel mixture composed of 24% HN and 1%  $H_2O$  in  $N_2H_4$  was tested for compatibility and radiation resistance. The pressure buildup due to irradiation was independent of container material, but CRES-347 was not compatible with the nitrate mix even without irradiation. The pressure rose in the CRES-347 bomblet eight times faster than in the other bomblets. The rate of radiation-induced decomposition of the nitrate fuel mix was 50–60% higher than the rate of neat hydrazine.

In de-aerated aqueous solutions,  $\gamma$  radiation decomposed hydrazine to ammonia and nitrogen [1330]. The results have been interpreted assuming that radiolysis of the solvent produced  $\cdot OH$  and  $H\cdot$  radicals, which abstracted hydrogen from hydrazine-forming hydrazyl radicals, which disproportionated to  $N_2 + 2NH_3$ . In distinctly alkaline solution, hydrazyl might also dissociate into  $N_2H_2^-$  and  $H^+$ . Aerated solutions decompose with the same  $G$  yield if the pH is below 9. In this case nitrogen is the sole reaction product. It is assumed that an  $HOO\cdot$  radical is formed that is as active as  $H\cdot$  in the destruction of hydrazine. The amount of gas formed by the radiolysis of liquid hydrazine could not be reduced by the addition of olefinic radical scavengers [1331].

The effect of irradiation is of importance for rocket propellants as well as structural materials and for the two in contact with each other. Gamma radiation instead of X-ray radiation was used for material-radiation compatibility studies to qualify hydrazine for long-term space missions. In one test at JPL with  $^{60}Co$  radiation with hydrazine in a titanium tank, more gas was formed at a low dose rate (5600 rad/h) than at a high dose rate (6160 rad/h) [1332]. After 10 Mrad, 60–80  $\mu mol$  of gas had formed per gram of hydrazine.

Gamma radiation was used to dissociate hydrazine and UV was used as a diagnostic tool to change the excited states of the free radicals thus formed. Hydrazyl free radicals were first generated in frozen hydrazine in sealed quartz ampoules at 77 K by  $\gamma$ -irradiation, then photolyzed by UV light in a wavelength where undissociated hydrazine does not absorb and then measured by EPR. The UV used was filtered to provide maximum intensity between 280 and 400 nm or between 340 and 400 nm. Hydrazine does not absorb in these regions. When the frozen samples were exposed to UV light, the hydrazyl radical concentration decreased. The radical concentration and the concentration-time profile were observed at 77 to 194 K, and the activation energy of the recombination reactions could be determined [1333]. Although the free radicals were immobilized in a matrix of frozen hydrazine, there appeared to be a chain reaction by way of proton or electron exchange migration. The light-excited hydrazyl radical dissociated with the formation of diazene and a hydrogen atom, which abstracted another hydrogen from frozen hydrazine and propagated the chain reaction.

#### 4.7.2.1 Gamma-Ray Radiolysis of Hydrazine Solutions

The radiolysis of water produces  $\bullet\text{OH}$  radicals. The attack of  $\bullet\text{OH}$  radicals on hydrazine produced a short-lived intermediate with absorption at 230 nm, thought to be the hydrazyl radical. The half-life time was approximately 50  $\mu\text{s}$ . Extended observation showed that there existed another longer-lived species that absorbed at the same wavelength and decayed by a first-order acid- or base-catalyzed reaction with a half-life time of approximately 5 ms. There was supportive evidence that the species could have been triazene [1334]. Triazene can participate in the following acid-base equilibria:

The  $\text{p}K$  values were determined from the dependence of the first-order rate constant on pH, from the dependence of initial absorbance on pH, and from the dependence of the first-order rate constant on temperatures at constant pH. The rate constants for the decomposition of the acidic and basic forms of triazene in solution were

$$\text{triazenium ion} \quad k = 1.97 \times 10^{11} e^{(-12600/RT)} \text{ s}^{-1}$$

$$\text{triazenide ion} \quad k = 2.14 \times 10^{14} e^{(-19200/RT)} \text{ s}^{-1}$$

Triazene itself, which is relatively stable in comparison to its conjugate acid and base forms, has a rate constant of approximately  $0.001 \text{ s}^{-1}$  at 297 K. The global rate constant can be expressed as a function of pH by

$$k = \frac{133}{\left(1 + \frac{K_1}{[\text{H}^+]}\right)} + \frac{2}{\left(1 + \frac{[\text{H}^+]}{K_2}\right)} \text{ s}^{-1}$$

where  $K_1 = 1.12 \times 10^{-5}$  and  $K_2 = 4.27 \times 10^{-12}$  ( $\text{p}K_1 = 4.95$  and  $\text{p}K_2 = 11.37$ ). The decomposition of triazene is catalyzed by phosphate ions. If one assumes that triazene has a linear structure as shown in the preceding reaction scheme, a rapid proton migration or tautomerism must occur. On the other hand, since the spectrum of the reaction mixture showed no absorption characteristics of the  $-\text{N}=\text{N}-$  azo group (which brightens the world of dyestuff chemistry with such beautiful colors), the cyclic structure cyclo-triazene

cannot be ruled out. However, isotope distribution in the products did not support this theory.

The kinetics of oxidation of hydrazine and some of the intermediates can be identified by generating an oxidant in an aqueous solution *in situ* by pulse radiolysis. In an aqueous solution, pulse radiolysis generates hydroxyl radicals,  $\bullet\text{OH}$  [563]. The rate of reaction of hydrazine with hydroxyl radicals was found to depend on the state of protonation of hydrazine or hydrazinium ions, respectively:  $k(\text{OH} + \text{N}_2\text{H}_4) = 1.4 \times 10^{10} \text{ dm}^3 \text{ mol}^{-1} \text{ s}^{-1}$ , whereas  $k(\text{OH} + \text{N}_2\text{H}_5^+) = 1.0 \times 10^9 \text{ dm}^3 \text{ mol}^{-1} \text{ s}^{-1}$ . Various intermediates were observed by UV absorption spectrometry and tentatively identified as hydroxyl radical, tetrazane, and triazene. Up to that time, these intermediates had not yet been observed in solution, but only in the gas phase. The radiolysis products, ammonia and hydrogen, have a pronounced effect on the overall reaction rate, because in their absence the radiolysis of hydrazine is much faster.

If the radiolysis is conducted at pH = 9, an intermediate that absorbs at 230 nm and decays through a second-order reaction is observed, presumed to be the hydrazyl radical. In neutral or acidic solutions, not only hydrazine, but also the hydrazyl radical becomes protonated. Its pK is 7.1, somewhat less basic than hydrazine itself (pK = 8.07). The second-order decay of hydrazyl radicals is postulated to form tetrazane, which decomposes in unimolecular reaction to triazene and ammonia:

Triazene decays by first-order kinetics, presumably to ammonia and nitrogen. The decay rate is markedly dependent on pH, resulting in more rapid decomposition of  $\text{N}_3\text{H}_3$ , or rather  $\text{N}_3\text{H}_4^+$  in acidic solution.

According to Lefort and Haissinsky [1330], the irradiation of hydrazine in deoxygenated water with  $\gamma$  radiation leads to the formation of ammonia and nitrogen. The radiolysis products of water ( $\bullet\text{H}$  and  $\bullet\text{OH}$  radicals) are assumed to react with hydrazine to form a hydrazyl radical  $\bullet\text{N}_2\text{H}_3$ , which then undergoes further decomposition. If oxygenated aqueous solutions are irradiated, the sole product is nitrogen. At pH levels above 9, an  $\text{HOO}\bullet$  radical is also assumed to take part in the reaction, and the mechanism may be like that of hydrazine autoxidation. Some solutions were also irradiated with  $\alpha$  particles in place of  $\gamma$  radiation, but in these tests ammonia was always observed as a product.

The  $\gamma$  radiolysis of hydrazine solutions in water leads to both hydroxyl radicals and hydrogen peroxide. For continued radiolysis, a stationary  $\text{H}_2\text{O}_2$  concentration develops, and  $\text{H}_2\text{O}_2$  itself acts as radical scavenger. The hydrogen yields in acidic and neutral solutions can be explained by the equation [1325]

$$G(\text{H}_2) = G_{\text{H}_2} + G_{\text{red}} - G_{\text{H}_2\text{O}_2}$$

where the component  $G_{\text{red}}$  is contributed by radiolysis of hydrazine:

$$G(-\text{N}_2\text{H}_4)^* = G_{\text{red}} + G_{\text{OH}} = 5.2$$

The rate constant  $k(\text{N}_2\text{H}_5^+ + \text{H}^\bullet)$  has been found to be  $2.5 \times 10^4 \text{ L mol}^{-1} \text{ s}^{-1}$  at pH = 0 and  $1.2 \times 10^5 \text{ L mol}^{-1} \text{ s}^{-1}$  at pH = 6. For comparison, the rate constant of ion recombination  $k(\text{N}_2\text{H}_5^+ + \text{e}^-_{\text{aq}})$  at pH = 6 is equal to  $1.5 \times 10^7 \text{ L mol}^{-1} \text{ s}^{-1}$ . The low yields of radiolysis in very alkaline (pH = 13) solutions can be attributed to the slow rate of the reaction  $\text{N}_2\text{H}_4^+ + \text{e}^-_{\text{aq}}$ .

The Arrhenius plot for reaction rates of  $\bullet\text{OH}$  with  $\text{N}_2\text{H}_4$  and  $\text{N}_2\text{H}_5^+$  did not give a straight line, and activation energies could not be derived. The products of the  $\bullet\text{OH}$  reactions are  $\bullet\text{N}_2\text{H}_3$  and  $\bullet\text{N}_2\text{H}_4^+$ . Recombination of  $\bullet\text{N}_2\text{H}_3$  has the same temperature dependence as the recombination of  $\bullet\text{OH}$  free radicals ( $k = 2 \times 10^9 \text{ L mol}^{-1} \text{ s}^{-1}$  at 293 K) and leads to tetrazene. Tetrazene then decomposes first by a first-order process to triazene and then to nitrogen and ammonia. Decomposition of triazene does not go directly from the neutral species but only via the cationic or anionic forms,  $\text{N}_3\text{H}_4^+$  or  $\text{N}_3\text{H}_2^-$ . The decomposition of triazene is acid- and base-catalyzed over the entire temperature range tested from 293 to 473 K. The absorption maximum of solvated electrons increases from 700 nm at 288 K to 970 nm at 473 K.  $\bullet\text{N}_2\text{H}_3$  has a maximum absorbance at 230 nm and  $\bullet\text{N}_2\text{H}_4^+$  has a weaker absorbance also at 230 nm. Triazene absorbed with a  $\lambda_{\text{max}}$  at 225 nm.

Rate constants for the reactions of  $\text{e}^-_{\text{aq}}$  and  $\bullet\text{OH}$  with  $\text{N}_2\text{H}_4$  and  $\text{N}_2\text{H}_5^+$  in liquid water at temperatures up to 473 K (200 °C) have been measured by pulse radiolysis [1335, 1336]. Linear Arrhenius plots for the reactions of  $\text{e}^-_{\text{aq}}$  gave  $k(293) = 10^6$  and  $1.6 \times 10^8 \text{ dm}^3 \text{ mol}^{-1} \text{ s}^{-1}$ , and  $E_a = 13.5$  and  $18.2 \text{ kJ/mol}$ , respectively. H is the product of the reaction with  $\text{N}_2\text{H}_5^+$ . The  $\text{pK}_a$  of  $\text{N}_2\text{H}_5^+$  decreased linearly with temperature from 8.1 at 293 K (20 °C) to 4.2 at 473 K (200 °C). The products of the  $\bullet\text{OH}$  reactions were  $\bullet\text{N}_2\text{H}_3$  and  $\bullet\text{N}_2\text{H}_4^+$ , respectively, and the  $\text{pK}_a$  of  $\bullet\text{N}_2\text{H}_4^+$  also decreased with increasing temperature. The self-reaction of  $\bullet\text{N}_2\text{H}_3$  showed the same temperature dependence as that of  $\bullet\text{OH}$  with  $k(293) = 2 \times 10^9 \text{ dm}^3 \text{ mol}^{-1} \text{ s}^{-1}$ . The product of this reaction was tetrazene. Up to 473 K (200 °C) the data were consistent with successive eliminations of  $\text{NH}_3$  to form triazene and then  $\text{N}_2$ . The pH-dependent kinetics of these processes indicated that the decomposition of triazene  $\text{H}_2\text{NN}=\text{NH}$  is acid- and base-catalyzed over the whole temperature range.

The rate of reaction of oxygenated water with hydrazine in a pulse radiolysis reactor at pH = 10.3 was  $k = (3.8 \pm 0.1) \times 10^6$  and the activation energy was unusually low [1337]. This low value was interpreted to indicate the formation of  $\bullet\text{N}_2\text{H}_3\text{O}_2$ . In irradiated oxygenated solutions, hydrazine could be destroyed by a short chain reaction that may be terminated by radical-radical reactions. Complexing metal ions by adding EDTA shortened the chain. Metal ions present as contaminants accelerated the chain propagating reactions more than the termination steps.

The radiation-induced decomposition by  $^{60}\text{Co}$   $\gamma$  rays of oxygen-saturated aqueous solutions of hydrazine has been measured over the pH range 3.5 to 11.7 [1338]. A reaction set has been proposed that accounts for the experimental observations based on the decomposition proceeding by a pH-dependent chain reaction propagated by hydrazyl radicals (specifically  $\bullet\text{N}_2\text{H}_3$ ) reacting with  $\text{O}_2$  and the resulting

$\text{HO}_2/\text{O}_2^-$  radicals oxidizing the hydrazine to hydrazyl radicals ( $\bullet\text{N}_2\text{H}_4^+/\bullet\text{N}_2\text{H}_3$ ). Chain termination is probably via the self-reactions of  $\text{HO}_2/\text{O}_2^-$ . The pH dependence of the chain length was consistent with (a)  $\text{HO}_2/\text{O}_2^-$  having different reactivity toward  $\text{N}_2\text{H}_4/\text{N}_2\text{H}_5^+$  in the propagating step and (b) the known pH dependence of the termination reaction. There was no evidence that  $\bullet\text{N}_2\text{H}_4^+$  is a chain carrier.

#### 4.7.2.2 Decomposition of Hydrazine by $\alpha$ Radiation

The decomposition of hydrazine by  $\alpha$  rays leads to nitrogen, ammonia, and hydrogen:

It has been proposed that in the presence of a large excess of hydrogen atomic hydrogen is formed first, which then results in the protolysis of hydrazine [1339]:

#### 4.7.3 Hydrazine Decomposition in Glow Discharges

As already mentioned in the section on hydrazine synthesis from ammonia or from the elements in a glow discharge, hydrazine will decompose under these conditions of synthesis very rapidly, and at best a low stationary concentration of hydrazine can be obtained by passing ammonia through a glow discharge. Glow discharges with and without internal electrodes have been used to study the decomposition kinetics of hydrazine at low pressure in the gas phase. It was possible to prove the existence of tetrazene,  $\text{N}_4\text{H}_4$ , and triazene,  $\text{N}_3\text{H}_3$ , by the mass spectrometry of hydrazine glow discharge products [342]. If hydrazine vapor was decomposed by electrodeless discharge near the sampling orifice of a mass spectrometer, the following species were observed:  $\text{H}\bullet$ ,  $\text{H}_2$ ,  $\text{N}$ ,  $\bullet\text{NH}_2$ ,  $\text{NH}_3$ ,  $\text{N}_2$ ,  $\text{N}_2\text{H}_2$ ,  $\text{N}_2\text{H}_4$ , and  $\bullet\text{N}_2\text{H}_3$ . If the products of the microwave glow discharge were first condensed in a liquid nitrogen trap and then fractionated by evaporation after removing the liquid nitrogen from the cold trap, tetrazene  $\text{N}_4\text{H}_4$  could be observed in addition to the aforementioned species. Since no tetrazene was present in the gaseous products of the direct sample, it must have formed by recombination in the condensate as the condensate thawed out. Diazene  $\text{N}_2\text{H}_2$  was also observed as a discrete mass peak that had about the same volatility as ammonia. It was found that  $\text{N}_4\text{H}_4$  evaporated at a somewhat lower temperature than  $\text{N}_3\text{H}_3$ . The least volatile species in the cold trap was the undecomposed hydrazine. Studies of the ionization potentials of various NH compounds in the mass spectrometer also allowed estimation of bond energies (Section 2.3.3).

Diazene has been obtained by the decomposition of hydrazine in a glow discharge and condensing the decomposition products immediately on a liquid-nitrogen-cooled calcium fluoride window [1340]. The yellow deposit, which contained up to 20% di-

azene in a matrix of ammonia, was indefinitely stable at liquid nitrogen temperature. The IR spectrum of the solid at 82 K agrees with the planar structure predicted for diazene, and the molecule appears to be principally in the *cis* form. A cold trap cooled with dry ice was inserted between the glow discharge tube and the liquid-nitrogen-cooled window. When the condensate on the window was allowed to warm up, the absorption bands characteristic of diazene, such as those at 2898, 3095, and  $3205\text{ cm}^{-1}$ , disappeared. Mass spectrometric analysis of the evolved gas showed diazene, ammonia, hydrogen, and nitrogen.

Even at room temperature, diazene vapor diluted with ammonia (prepared by microwave discharge in hydrazine) was surprisingly long lived [1239]. Based on absorption measurements at 345 nm, a wavelength characteristic of  $\text{N}_2\text{H}_2$ , the half-life time was on the order of several minutes. The fact that  $\text{N}_2\text{H}_2$  is not strongly paramagnetic and other data indicate the possibility of a singlet rather than a triplet for the ground state of the molecule.

A yellow deposit has also been observed on a cooled surface in the electrodeless discharge (0.2 MHz) in flowing (10 cm/s) hydrazine vapor [1341]. It has been postulated that this deposit is tetrazane, formed by the recombination of two hydrazyl radicals. A mass spectrometer analysis showed it consisted of 84 vol.-% nitrogen and 16% hydrogen. However, no further proof for this hypothesis was offered, and the compound decomposed on warming.

In another series of glow discharge experiments, hydrazine vapor was decomposed at 1.93 kPa (14.5 mm Hg) and 298 K with 19–60 W of power applied to electrodes 75 mm apart [1342, 1343]. The discharge current (19 to 60 W) and the residence time (0.4 to 2.8 s) were varied, and measurements were made of the light emission at different wavelengths, the fraction of hydrazine decomposed, and the decomposition product composition. Sixty-five percent of the hydrazine was found to decompose within 0.16 A s. The strongest line in the decomposition spectrum was the  $\text{N}_2$  emission at 337.13 nm. Adjacent to this line was strong NH emission at 336.0 nm. Two weak lines at 516.62 and 570.7 nm were assigned to the  $\cdot\text{NH}_2$  radical. These do not stem from ammonia decomposition, because ammonia has a higher dissociation energy (4.52 eV) than hydrazine (3.30 eV), and insufficient energetic electrons were available to decompose ammonia. Also, the hydrazine glow discharge could be sustained only above a threshold voltage applied to the electrodes. Below this voltage no glow discharge was observed, whereas above this voltage at least 64% of the hydrazine decomposed. The decomposition mechanism proposed by Logan agrees with photolytic decomposition studies.

Besides by electrode-supported and electrodeless discharges, hydrazine can be decomposed in silent discharges. The emission spectra obtained from silent discharge in hydrazine have been recorded and compared to those of ammonia [1344]. Between 500 and 800 nm three previously unreported diffuse peaks were reported, with maxima at 525, 638, and 756 nm, which came most likely from molecules with more than

two atoms, possibly  $\text{N}_2\text{H}_3$ ,  $\text{N}_2\text{H}_2$ , or  $\text{N}_2\text{H}_4$  itself. Several papers on the decomposition of hydrazine in a high-frequency glow discharge plasma have been published [1345–1348].

The plasma generated in the glow discharge of hydrazine vapor can be exhausted through a nozzle in a plasma thruster operating on hydrazine decomposition products [1349, 1350]. Preliminary tests were conducted to examine a reaction mechanism using pulsed or stationary AC discharge plasma instead of pelletized catalysts in a rocket-type reaction chamber. In the reaction chamber filled with hydrazine, a sudden increase in temperature and pressure was observed immediately after the activation of a plasma discharge.

#### 4.7.3.1 Hydrazine Decomposition by Electron Beams

In a glow discharge electrons undoubtedly contribute effectively to hydrazine decomposition, but it is not possible to separate their effect from those of the other ions in the plasma. As part of the studies on hydrazine formation by the pulse radiolysis of ammonia, the decomposition of hydrazine by  $\beta$  radiation was also studied. It is this unwanted decomposition reaction that limits the hydrazine yield in the pulse radiolysis of ammonia.

Ionization of a molecular beam of hydrazines by electron bombardment is the most common method for the preparation of a sample for analysis by mass spectrometry. Under these conditions, not only will the parent molecule become ionized, but, depending on the energy of the electrons, the molecule will also be fragmented into smaller radicals and short-lived intermediates. The appearance potentials of various  $m/e$  peaks are summarized in Section 3.6.12 on mass spectrometric analytical methods.

#### 4.7.3.2 Electron Beam Bombardment of Pure Hydrazine in Condensed Phase

Hydrazine was sublimed on a liquid-nitrogen-cooled cold finger and subjected to the discharge from a Tesla coil with approx. 20-keV electrons and a mix of anions of undetermined energy [1351]. The frozen hydrazine did not discolor permanently, even after the longest exposure to radiation. It did appear to turn slightly blue for an instant, but this color could not be stabilized. Even when replacing the  $\text{LN}_2$  with liquid helium, the bombarded frozen hydrazine remained colorless. The cold finger condensate could be fractionated by allowing the most volatile species to sublime first. The reactions occurring during thawing were interrupted by refilling the cold finger with  $\text{LN}_2$  and the absorption spectra in the visible range were recorded after each step and showed distinct changes as the thawing progressed. The  $\text{N}_2/\text{H}_2$  ratios in the ultimately evolved gas depended on the thawing sequence. This indicated that the gases formed not as a result of particle beam irradiation, but as a result of some intermediates that were stable at 77 K but followed different decomposition paths, depending on the thawing sequence.

Although  $\gamma$  radiolysis and fast electron radiolysis by pulsed radiation in the microsecond range was observed previously, the first pulsed electron radiolysis investigation of hydrazine in the nanosecond range found that 3-ns pulses of 600-keV electrons provided about  $10^{14}$  electrons per pulse [1323]. A spectrum in the range 300–1100 nm was recorded immediately after the pulse and again 4  $\mu$ s later. The transient spectrum measurement was not extended below 310 nm because of the strong absorption of hydrazine. The maximum of the spectrum that was recorded immediately after passage of the pulse was located beyond 1100 nm, outside the range of the spectrometer. A similar spectrum had previously been observed using a 4.5- $\mu$ s electron pulse and attributed to the solvated electron in hydrazine [1236]. This assignment was now confirmed using biphenyl as an electron scavenger. The ions present had a stronger effect on the electron decay than electron-hydrazine solvent interaction. Whereas solvated electrons can easily be generated and observed forever in anhydrous liquid ammonia by dissolving some alkali metal, the blue color due to the solvated electron can be observed in hydrazine for only a few seconds. Hydrazine very rapidly forms hydrazides of the alkali metals that are very explosive, even in solution. There is thus no easy way to observe solvated electrons in hydrazine other than by using equipment that operates in the microsecond range or faster. In the solution that contained hydrazinium(1+) chloride, there was also an absorption band from 330 to 450 nm with a peak at 370 nm. This band has not yet been identified. A similar, weaker one could also be observed in pure hydrazine.

#### 4.7.3.3 Electron Beam Bombardment of Hydrazine Vapors

Electron bombardment of hydrazine vapors has practical implications: The data may be useful in optimizing the sensitivity of mass spectrometers in the analysis of hydrazine in air or other atmospheres. Electron bombardment ionization or low-pressure samples in the sample inlet of mass spectrometers precedes the separation of ions in crossed electrostatic and magnetic fields.

Nearly monochromatic electron beams can be generated with good uniformity of energy levels and aimed at the vapor of  $X-NH_2$  molecules ( $X = H, NH_2, OH, CH_3$ ) capable of splitting off amino radicals or ions. When setting (fixing) a QMS to the  $m/e$  of  $NH_2^-$  ions and tuning the energy level of the electron beam, it is possible to generate a maximum intensity of  $NH_2^-$  at a certain resonant energy level of low-energy (0.1–10 eV) electrons where electrons preferentially attach themselves to the dissociated molecular fragment, rather than splitting it into smaller pieces. Surprisingly, ammonia, hydrazine, hydroxylamine, and methylamine all gave very similar  $NH_2^-$  appearance potentials, in contrast to potentials predicted from theory that would essentially parallel the  $H_2N-X$  bond energy [1352]. In crossed-beam experiments with ammonia or hydrazine at up to 23 eV, fluorescence from excited fragments was observed at low pressure and the emitting species were identified by spectroscopic measurements [1353]. The threshold energies at which certain fragments began to appear are listed in Table 57.

**Table 57:** Threshold energies for appearance of light-emitting species in glow discharges.

| Vapor                         | Primary reaction                                                                                                                   | Energy, eV |
|-------------------------------|------------------------------------------------------------------------------------------------------------------------------------|------------|
| N <sub>2</sub> H <sub>4</sub> | N <sub>2</sub> H <sub>4</sub> → NH <sub>2</sub> *( <sup>2</sup> A <sub>1</sub> ) + NH <sub>2</sub> ( <sup>2</sup> B <sub>1</sub> ) | 3.87       |
| N <sub>2</sub> H <sub>4</sub> | N <sub>2</sub> H <sub>4</sub> → NH*( <sup>3</sup> Π) + NH <sub>3</sub>                                                             | 5.92       |
| N <sub>2</sub> H <sub>4</sub> | N <sub>2</sub> H <sub>4</sub> → NH*( <sup>3</sup> Π) + NH( <sup>3</sup> Σ) + H <sub>2</sub>                                        | 10.07      |
| N <sub>2</sub> H <sub>4</sub> | N <sub>2</sub> H <sub>4</sub> → NH*( <sup>3</sup> Π) + NH <sub>2</sub> ( <sup>2</sup> B <sub>1</sub> ) + H                         | 10.42      |

Data source: [1353]

It was thought remarkable that the (<sup>1</sup>Π) state of NH is not produced by electron impact on hydrazine. Similar appearance potential measurements are important for the optimization of mass spectrometers as analytical instruments.

Electron-impact dissociation of other nitrogen species, including hydrogen azide or methylamine in addition to hydrazine or ammonia, also produced excited NH(A<sup>3</sup>Π) or NH(c<sup>1</sup>Π) radicals [1354]. The triplet excited state of the parent compound contributes to the formation of the triplet NH(A<sup>3</sup>Π) near the threshold. The threshold of the reaction

was observed at 10.4 eV, in agreement with the results of theoretical calculations and experimental results reported by other investigators. More energetic electrons up to 50 eV were used to study the formation and internal energy distribution of NH fragments produced from dissociation of hydrazine or methylamine at 0.013 Pa (~10<sup>-4</sup> mm Hg) [1355]. Both NH(A<sup>3</sup>Π) and NH(c<sup>1</sup>Π) were found in either reaction and identified by their emission spectra at 336 nm. In the electron-impact dissociation of hydrazine, the observed rotational temperature of the *v*' = 0 level of the NH(A) state was about twice as high as that of the NH(c) state. The onsets of NH(A<sup>3</sup>Π) and NH(c<sup>1</sup>Π) formation from hydrazine were at 10.8 ± 0.6 and 11.9 ± 0.7 eV, respectively. Even higher electron energies (10–270 eV) were used to study the electron-impact dissociative ionization of ammonia, hydrazine, and MMH [402]. The apparatus consisted of (1) pulsed electron and molecular beams, (2) a field-free ionization volume, (3) two-stage high-voltage ion extraction, and (4) multi-channel mass detection. Thirty-five parent and fragment ions were detected and the appearance potentials for electron impact ionization were compared to those obtained by photoionization. All measurements were made in a crossed electron-molecular beam apparatus using pulsed extraction and time-of-flight mass detection to ensure field-free excitation and high collection efficiency for energetic ions. The molecular beams were jet-cooled to obtain uniform

initial energy levels. The measured cross sections for total ionization at 70 eV were  $2.35 \text{ \AA}^2$  for ammonia,  $3.76 \text{ \AA}^2$  for hydrazine, and  $4.20 \text{ \AA}^2$  for MMH. In a continuation of this study, electron energies for electron impact dissociative ionization were varied from the ionization thresholds to 260 eV [1356]. Molecules at room temperature underwent more fragmentation upon ionization, and the distribution of partial cross sections shifted toward smaller fragment ions. The partial cross sections of energetic ions need to be corrected for detection (in)efficiency, which drops for higher-energy ions.

In the gas phase, the radiolysis of hydrazine leads to hydrogen, nitrogen, and ammonia [1357]. Hydrazine vapor was irradiated under dynamic conditions at a pressure of  $6 \times 10^{-3} \text{ mm Hg}$  (0.8 Pa) by a beam of electrons, the energy of which could be varied between 10 and 100 eV. Another series of experiments was carried out by the irradiation of hydrazine vapor under static conditions at a pressure of 14 mm Hg (1.9 Pa) by  $\alpha$  rays in an apparatus that also enabled the effect of an electric field on the radiolysis to be determined. The results obtained seemed to indicate that the radiolytic decomposition of  $\text{N}_2\text{H}_4$  was initiated by two primary acts: an excitation producing  $\text{N}_2$  and  $\text{H}_2$ , and an ionization producing  $\text{N}_2$  and  $\text{NH}_3$ . At low pressures these two mechanisms are of comparable importance; at higher pressures the latter one initiating a chain reaction becomes predominant.

Different approaches have been proposed for the study of bond breakage probabilities under electron impact, including the calculation of stabilities, rupture coefficient, and indices of fragmentation [1358].

#### 4.7.4 Hydrazine Decomposition by Atomic Hydrogen

Most studies on the decomposition of hydrazine under the influence of proton beams ( $\beta$  radiation) were conducted in the vapor phase. However, with the use of hydrazine hydrate in the primary steam loop of nuclear reactors, interaction with atomic hydrogen in the liquid aqueous phase was becoming of increasing interest.

##### 4.7.4.1 Hydrazine Decomposition by Atomic Hydrogen in Vapor Phase

Atomic hydrogen can be used as a selective reagent to initiate hydrazine decomposition, and numerous publications deal with this method. Actually, these papers should be listed among the methods used to generate hydrogen atoms, such as glow discharge or photolysis [1301]. However, the method is sufficiently unique to deserve a section of its own. In a similar fashion, atomic oxygen is also used to initiate decomposition of hydrazine with the subsequent formation of water. These studies are discussed in the section on hydrazine combustion mechanisms (Section 4.14). A convenient source of atomic hydrogen is the photolysis of hydrazine [1301].

Numerous publications deal with the decomposition of hydrazine under the influence of hydrogen atoms [545, 1199, 1219, 1221, 1222, 1359]. Over the years, experimental

techniques have been refined, and new methods of analysis, such as ESR, have been applied to study the free radicals formed in the process.

The luminescent reaction of hydrazine with atomic hydrogen was studied in flowing gas systems [1360, 1361]. The emission is due to  $\text{NH}_2$  radicals apparently produced by the process

Estimates of the emission quantum yield showed that this is a relatively minor process. The absorption spectrum showed an unexpectedly high concentration of  $\text{NH}_2$  radicals in the reaction zone. This is consistent with the other known facts if the process

becomes important when the  $[\text{H}]/[\text{N}_2\text{H}_4]$  ratio is large.

When hydrogen atoms generated in a glow discharge were mixed with a molecular beam of hydrazine vapor, a reaction with the formation of ammonia and permanent gases ( $\text{N}_2 + \text{H}_2$ ) took place. At the point of impingement of the jets, a weak green fluorescence could be observed [1359]. The mixing zone also heated up considerably from the heat liberated by the reaction. The hydrogen atom concentration was measured by the heat of recombination when a platinum foil (Langmuir probe) was exposed to the gas. The first attempt to explain the mechanism of atomic hydrogen reactions with hydrazine followed the path of thoughts previously established during ammonia photolysis:

One convenient way to study free radicals involved in reactions is by recording their emission spectra. Hydrogen atoms were generated in a glow discharge and interacted with a molecular beam of hydrazine vapor at a pressure of 133 Pa (1 mm Hg) [545]. An  $\text{NH}_2$  band of medium intensity and  $\text{NH}$  bands of weak intensity were observed in emission. Hardly any undecomposed hydrazine was found in the condensate, but 30–55% of the theoretically possible ammonia was condensed as such. No emission spectra could be recorded when ammonia was substituted for the hydrazine. With atomic oxygen very intense emission spectra were observed.

ESR was used to measure the rate of reaction of hydrogen atoms with hydrazine [1221]. Although a reaction stoichiometry was not deduced because no gas analysis was performed, a possible reaction sequence is also being proposed for this mode of hydrazine decomposition. The first step is most likely a hydrogen abstraction

(Reaction (10) in Figure 38

The hydroxyl radical can then follow one of two reaction paths

(Reaction (4) in Figure 38

or

(Reaction (11) in Figure 38

Since the experimental conditions were such that the hydrazine concentration was much higher than the hydrogen atom concentration,

was considered more likely. Because it lacks an exact stoichiometry, the pre-exponential factor obtained in this study is less accurate than the activation energy. The activation energy was obtained from the slope of the rate constant straight line in an Arrhenius plot and agreed well with those reported by other authors (Table 51). The main difference in the pre-exponential factor may be due to the use of a fast flow system in [1219] and [1221], as opposed to a stirred reactor used by previous investigators [1222]. In a similar study in which a stream of atomic hydrogen was generated by subjecting a mixture of 0.5%  $\text{H}_2$  and 99.5% He to a high-frequency electrodeless discharge (2375 MHz, 100 W), the reaction of hydrogen atoms with hydrazine vapor was studied in a flow system by ESR spectroscopy at 304–505 K and 0.23–0.33 kPa with contact times from 0.5 to 10 ms [1362]. By repeating the test at different temperatures, the activation energy of the reaction was determined by a discharge flow method and ESR as  $9.2 \pm 0.9$  kJ/mol [1363].

The absolute rate parameters of the reaction of atomic hydrogen with hydrazine were measured using flash photolysis and measurement of atomic hydrogen by means of resonance fluorescence [1223]. No secondary reactions involving hydrogen atoms as a reactant or product interfered with these measurements.

It was difficult to determine rate constants for several reactions of importance in hydrazine decomposition [1219]. The results were already summarized in Table 53. The hydrogen atoms were generated in a separate chamber by microwave induction and then mixed with hydrazine vapor at 213–473 K and 133–1330 Pa (1–10 mm Hg) in a flow system. The composition of the decomposition products varied with the ratio of atomic hydrogen to undecomposed hydrazine. As long as this ratio did not exceed 5, the following stoichiometry of the decomposition reaction was observed:

When the effluent of the mixing zone was monitored with a TOF mass spectrometer at  $m/e = 16$  (the molecular weight of the amino radical), it increased slightly from a background current to an intermediate value if hydrazine only was introduced. How-

ever, as soon as the hydrogen discharge was energized, the  $\bullet\text{NH}_2$  radical concentration jumped to more than twice this value. This is a distinct proof for the presence of  $\bullet\text{NH}_2$  radicals as the result of hydrogen atom interaction with hydrazine. Besides  $\bullet\text{NH}_2$ ,  $\bullet\text{N}_2\text{H}_3$  and  $\text{NH}$  radicals were observed in smaller concentrations;  $\bullet\text{N}_2\text{H}_3$  could be identified by monitoring mass number 31 while reacting molecular beams of hydrogen atoms and hydrazine. Further proof of the hydrogen abstraction from hydrazine was provided using deuterium instead of hydrogen atoms:

In this test the ion current at  $m/e = 3$  increased as soon as the experiment was initiated.

The rate constant obtained for the reaction  $\text{H}\bullet + \text{N}_2\text{H}_4 \rightarrow \bullet\text{N}_2\text{H}_3 + \text{H}_2$  is shown in Table 53. Even though the activation energy is the highest of all reported to date, the rate constants reported by Gehring agree well with the results obtained by [1221] but do not agree with those by [1222]. A direct comparison is difficult because the conditions of reaction were slightly different. Gehring and co-workers [1219] deemed the direct decomposition of diazene [Reaction (9) in Figure 38] as very unlikely. Instead, they assumed a rate of  $5 \times 10^{12} \text{ cm}^3 \text{ mol}^{-1} \text{ s}^{-1}$  for the reaction

to explain the disappearance of  $\text{NH}$  without intermediate formation of  $\text{N}_2\text{H}_2$ . Concentration profiles for nine species in the reaction  $\text{H}\bullet + \text{N}_2\text{H}_4$  were calculated for the first 3 ms of reaction time. Calculated curves agreed well with experimental TOF mass spectrometer data (to be compared also to the results obtained by abstraction of hydrogen from hydrazine [346, 347]).

The energy profiles of reactions of  $\text{H}_2\text{NN}\bullet\text{H}$  and  $\text{H}_2\text{NNH}_2^{\bullet+}$  with  $\text{H}\bullet$  in the gas phase were studied using a modified G2 (MP2) *ab initio* method. This method has been used to obtain bond dissociation energies, proton affinities, and heats of formation of hydrazine and radicals and radical ions derived therefrom [567]. During the attack of  $\text{H}\bullet$  on  $\text{H}_2\text{NNH}_3^+$ , the rate of formation of  $\text{H}_2\text{NNH}_2^{\bullet+}$  by H abstraction from the  $\text{NH}_3^+$  end of the molecule has a very low activation energy, but in aqueous solution, solvation effects will lead to attack at both ends in comparable intensity.

A study of the hydrogen abstraction reaction  $\text{N}_2\text{H}_4 + \text{H} \rightarrow \text{N}_2\text{H}_3 + \text{H}_2$  using a direct *ab initio* dynamics method predicted four possible reaction channels caused by different structures of  $\text{N}_2\text{H}_4$  and different positions of hydrogen atom attack [1364]. The structures and frequencies at the stationary points and along the minimum energy paths were determined by computations. Thermodynamic data for reactants and intermediates were further refined based on theory. The rate constants are calculated in a temperature range of 220–3000 K. The calculated results showed that in the lower temperature range, the most favorable reaction channels are

and

while in the higher-temperature range

and

predominated. The calculated total rate constants of the four reaction channels were in good agreement with the available experimental data.

#### 4.7.4.2 Hydrazine Decomposition by Atomic Hydrogen in Liquid Phase

Hydrogen atoms were generated in aqueous solution within an EPR spectrometer cavity by pulse radiolysis with 3-MeV electrons from a van de Graaff accelerator, and the irradiated fluid was flowing through the sample chamber at a rate sufficiently high to completely replace the liquid between pulses [1365]. At 314.7 K, a scavenging constant of  $(5.8 \pm 1.9) \times 10^6 \text{ L mol}^{-1} \text{ s}^{-1}$  was measured directly for the reaction of  $\text{H}^\bullet$  with  $\text{N}_2\text{H}_5^+$ . From data taken over the temperature range 314–355 K the activation energy could be calculated as  $61.4 \pm 1.2 \text{ kJ/mol}$ . Based on these measurements, the acidity constant of the  $\text{N}_2\text{H}_5^+$  ion over the range 273–353 K can be calculated from

$$\text{p}K_{\text{a}} = \frac{2600 \pm 30}{T} - (0.771 \pm 0.099) \quad T \text{ in K}$$

which gives  $\text{p}K_{\text{a}} = 7.95$  at 298 K. From the two preceding equations, then, the rate constant could be calculated for the reaction of  $\text{H}^\bullet$  with  $\text{N}_2\text{H}_4$  itself, which was found to be  $k = (6.74 \pm 0.23) \times 10^7 \text{ L mol}^{-1} \text{ s}^{-1}$  at 297.6 K with an activation energy of  $16.29 \pm 0.80 \text{ kJ/mol}$ . The reaction rate of  $\text{H}^\bullet$  with  $\text{N}_2\text{H}_4$  is consistent with hydrogen abstraction as the first step, giving  $\text{H}_2$  and  $^\bullet\text{N}_2\text{H}_3$ , like the gas-phase reaction. However, based on the relatively high activation energy and entropy of the reaction of  $\text{H}^\bullet$  with  $\text{N}_2\text{H}_5^+$ , an addition-fragmentation process has also been discussed.

#### 4.7.5 Hydrazine Decomposition by Molecular Beams and Vibrationally Excited Dinitrogen

Electronically excited dinitrogen  $\text{N}_2(\text{A}^3\Sigma_{\text{u}}^+)$  and vibrationally excited “active” dinitrogen molecules do not contribute significantly to the decomposition of hydrazine molecules in the nitrogen afterglow if the reaction with nitrogen atoms is the main reaction [1366]. The reaction of hydrazine with excited dinitrogen molecules may be a yield-limiting reaction in the attempts to synthesize hydrazine from the elements or from ammonia in a glow discharge, since it reverses the desired direction of synthesis. It may also take place if hydrazine is vented in the high atmosphere in areas where the

nitrogen afterglow can be seen. Some of these reactions of hydrazine with molecular excited species or ions also take part in a glow discharge (Section 4.7.3), but they are difficult to isolate when a host of species is zipping around between the electrodes. It would be better to extract a narrow range of particles and particle energies from a glow discharge and let them impinge on hydrazine vapor. The ratios of luminous intensity in the absence of hydrazine to that in the presence of hydrazine, measured at 580 nm [yellow glow due to recombination of  $N(^4S)$  atoms] were taken as an indication of reaction of N atoms with hydrazine. Similar ratios were measured at 253.7 nm in active nitrogen sensitized with mercury vapor. In all cases, and over a wide range of glow discharge currents, the presence of hydrazine quenched the emission intensity to a third to a fourth of the baseline luminous intensity.

It was observed that hydrazine vapor was completely destroyed when bombarded with active nitrogen at a flow rate of  $9 \times 10^{-5}$  mol/s [1367]. The tests were performed at 423 and 753 K and the rate of decomposition was 14% faster at the higher temperature. The results were interpreted to indicate that amino radicals are formed in only secondary reactions. The most probable mechanism for the reaction was proposed as

When modeling the thermodynamics and kinetics of sequential hydrogen abstraction reactions from hydrazine by nitrogen atoms, the dehydrogenation was divided into three steps:  $N_2H_4 + N$ ,  $N_2H_3 + N$ , and  $N_2H_2 + N$  [1368]. The thermal rate constants were calculated within the framework of canonical variational theory, with zero and small curvature multi-dimensional tunneling corrections. The reaction paths were computed, and the thermochemical properties were improved using another method. The first dehydrogenation step presented the lowest rate constants, equal to  $1.22 \times 10^{-20} \text{ cm}^3 \text{ mol}^{-1} \text{ s}^{-1}$  at 298 K.

#### 4.7.6 Hydrazine Decomposition Initiated by Hydrogen Abstraction

A direct *ab initio* dynamics study on the hydrogen abstraction reactions

predicted six possible reaction channels for  $NH_2$  abstraction and four for  $CH_3$  abstraction caused by the different  $N_2H_4$  isomers and various attacking orientations of foreign radicals in relation to  $N_2H_4$  [1369]. The structures and frequencies at the stationary points and the points along the minimum energy paths of all reaction channels were

calculated. The rate constants of these channels were calculated using the improved canonical variational transition-state theory with the small-curvature tunneling correction method. The calculated results showed that the favorable reaction channels were channels (n1) and (n4) as well as (c1) and (c3) in the whole temperature range. The rate constants of all channels for the two reactions were both in good agreement with the available experimental data, and corresponding three-parameter expressions in 220–3000 K are fitted as

$$k = 6.46 \times 10^{-15} (T/298)^{3.60} \exp(-386/T) \text{ cm}^3 \text{ mol}^{-1} \text{ s}^{-1}$$

for  $\text{NH}_2$  abstraction and

$$k = 1.04 \times 10^{-14} (T/298)^{4.00} \exp(-2037/T) \text{ cm}^3 \text{ mol}^{-1} \text{ s}^{-1}$$

for  $\text{CH}_3$  abstraction. Additionally, the long-range interaction between the H atom of X–H bond in foreign radicals and the lone pair on the non-reactive N atom of the transition states was further discussed to explain the various transition-state numbers of the two similar hydrogen abstraction reactions.

The kinetics of the reaction of  $\text{N}_2\text{H}_4$  with atomic oxygen depends on the initial conditions. In oxygen-rich systems, the rate constant shows a conventional positive temperature dependence, while in hydrazine-rich systems the dependence is negative in certain temperature ranges. A theoretical model was presented that adequately reproduced the experimental results for a hydrazine-rich environment, consisting of the hydrogen abstraction from the hydrazine dimer by an oxygen atom [1370]. The thermochemical properties of the reaction were computed using two quantum-chemical approaches. The kinetic data were calculated with the improved canonical variational theory using a dual-level methodology to build the reaction path. Energy potential wells on both sides of the reaction  $(\text{N}_2\text{H}_4)_2 + \text{O} \rightarrow \text{N}_2\text{H}_4 \dots \text{N}_2\text{H}_3 + \text{OH}$  were determined. A reaction path with a negative activation energy was found leading, in a temperature range of 250–423 K, to a negative dependence of the rate constant on the temperature, which was in good agreement with experimental measurements. The hydrazine dimer model provided significantly improved agreement with the experimental data and should be included in the mechanism of the global  $\text{N}_2\text{H}_4$  combustion process because it can be particularly important in hydrazine-rich systems.

#### 4.8 Analytical Mathematical Models of Hydrazine Decomposition

Besides the variety of experimental studies described in the preceding sections, some investigators have also conducted theoretical studies of mathematical models of hydrazine decomposition. These studies were greatly aided by the availability of digital computers in recent decades. The publications can generally be divided into equilibrium and non-equilibrium studies. Under practical conditions, such as in hydrazine decomposition reactors, equilibrium is rarely achieved, and the predictions of equi-

librium studies are of only limited value. On the other hand, non-equilibrium studies including kinetic rates for all reactions involved are not yet perfected, and, at best, rough approximations have been reported.

A theoretical kinetic study was conducted to investigate the effects of dihydrogen (present in pyro valve actuator blow-by gases) on hydrazine decomposition [1371]. Since hydrogen is a normal product of hydrazine decomposition, all reactions necessary to evaluate its effect on hydrazine decomposition chemistry were already in the original mechanism developed [1372]. The expanded kinetic mechanism consisted of 70 species interacting via a network of 452 reactions. Calculations indicated that  $H_2$  presence as an initial reactant in substantial amounts can dramatically impact the process of hydrazine decomposition. What was of particular interest, and somewhat surprising, was the extent to which molecular dihydrogen in the initial mixture was predicted to accelerate the decomposition of hydrazine. The change in hydrazine half-life from the baseline case (i.e., no  $H_2$  initially present) to the case where a 1 : 1  $H_2$ : $N_2H_4$  starting ratio exists was five orders of magnitude.

One of the kinetic analysis programs used for the study of hydrazine vapor decomposition was ReaxFF, which allows the valence interactions (bonds, angles, torsions) and charges to change continuously as bonds form and break in reactions. The instantaneous bond orders are determined from the bond distances that in turn determine the forces between the atoms. This program has been used to model the homogeneous decomposition of bulk hydrazine or MMH vapors, the decomposition of hydrazine in the presence of hydrogen peroxide, and the heterogeneous decomposition of hydrazine on catalytic surfaces Pt[100] and Pt[111] under various conditions [1373].

The most detailed and richly illustrated computational approach to date to hydrazine decomposition in the vapor phase and on the surface of iridium/alumina catalysts was based on gas-phase electronic structure theory calculations that included electron correlations and predicted that numerous molecular and free radical reactions could occur within the same energy range as the basic free radical pathways: N—N bond breaking around 272 kJ/mol (65 kcal/mol) and N—H bond breaking around 339 kJ/mol (81 kcal/mol) [1374]. The results suggested that a revision and more detailed approach to existing kinetics modeling were desirable, based on the energetics and the new elementary steps reported. A supported  $Ir_6$  octahedron model for the Shell 405 iridium catalyst was developed. Self-consistent field and electron correlation calculations (with core potentials and associated basis sets) illustrated a diverse chemistry for hydrazine on this catalyst model. The model catalyst enabled dramatically lower N—N and N—H bond cleavage energies and an even smaller barrier to breaking the N—H bond by  $NH_2$  abstractions. Thus, the low-temperature decomposition over the catalyst was interpreted in terms of consecutive  $NH_2$  abstractions to produce ammonia and nitrogen. The higher-temperature channel, which has  $H_2$  and  $N_2$  products, may be due to several simultaneous mechanisms. These mechanisms are successive N—H cleavages with surface H+H recombinations, and the same types of assisted  $H_2$  eliminations were found to occur in the gas phase.

#### 4.8.1 Equilibrium Calculations

Numerous thermochemical equilibrium computer programs have been described in the literature and applied to the problem of hydrazine and hydrazine derivative decomposition. The reason for discrepancies between equilibrium calculations and experimental results is that the equilibrium

is very slowly established, significantly slower than the hydrazine decomposition. In many cases the dwell time in a reactor is insufficient to establish equilibrium and the ammonia dissociation is lower than predicted by equilibrium calculations. There are also experimental errors, and it is difficult to obtain exact measurements of the degree of ammonia dissociation in the exhaust. Changes in the composition of the gas samples after they have been withdrawn from the reactor should not occur because the reaction is usually quenched by a cold probe, and the gases do not change composition when stored at room temperature.

Mollier-type diagrams have been calculated and graphed for hydrazine decomposition products at equilibrium temperatures of 865–1646 K and pressures up to 10 MPa, assuming 0–80% ammonia decomposition [1375]. These graphs have the advantage over other equilibrium calculations that a Beattie-Bridgeman-type EOS was used, which represents high-pressure data better than the ideal gas laws.

The highest operating temperature of actual hydrazine applications occurs in arcjets. Attempts have been made, with varying success, to model the plasma in the exhaust where hydrazine and ammonia are mostly dissociated, and the electron density is an important variable of the working medium. The residence time in an arcjet is usually too short to achieve equilibrium but, on the other hand, too long to assume frozen flow. Results of non-equilibrium numerical methods with separate electron and gas temperatures, including consideration of viscous flow properties and assuming laminar axisymmetric flow, were compared with experimental measurements of electron density with a Langmuir probe and heavy particle velocities with a TOF electrostatic probe [1376]. There are few reliable sets of thermodynamic and transport properties of nitrogen/hydrogen plasmas at very high temperatures and pressures. There are several more studies on arcjets, but they are beyond the scope of this chemistry book since the plasma could very well have started as a mixture of ammonia, nitrogen, and hydrogen instead of hydrazine, and one would not know the difference. One such model includes consideration of equilibrium dissociation/recombination, binary exchange, and ionization over a range of 1 MPa to 10 Pa and 300 to 15000 K [1377]. Equations are derived for electrical conductivity, viscosity, and thermal conductivity of the plasma flow.

## 4.9 Hydrazine Decomposition Flames

Many experimental investigations have been devoted to hydrazine decomposition flames. First, one could argue that this topic would be more accurately discussed in the preceding section under the overall heading “Homogeneous Vapor-Phase Decomposition.” However, hydrazine decomposition flames are discussed here because, although some investigators study the rate of combustion of *liquid* hydrazine strands, the rate-controlling phenomena still take place in the *vapor* phase. In a hydrazine decomposition flame, the liquid does not decompose *per se* but must vaporize first. The same is true for hydrazine combustion in the presence of oxidizers.

Unlike alkyl nitrate-based monopropellants like Otto Fuel II, hydrazine as a monopropellant is usually not burned in empty, hollow combustion chambers. As a minimum, if no catalyst is used to initiate and sustain hydrazine decomposition, there would be a thermal bed or a flame holder. Thus, flame speed studies have no practical value for hydrazine as a monopropellant and are done mostly to satisfy academic curiosity. Droplet decomposition of hydrazine sprays may have some practical applications in engines with discrete head spaces or in biplex engines where hydrazine is injected downstream of a catalytic pre-decomposition chamber and into a plenum chamber at very high pressures where it decomposes without the aid of a catalyst.

One significant advantage of liquid hydrazine over other monopropellants like nitromethane or some HAN-based monopropellants is that combustion does not propagate upstream from a hot reactor through the injector passages into the liquid propellant reservoir. The burning rate of hydrazine liquid through a liquid-filled line is too slow and the heat loss to the tubing wall will quench the propagation of a flame front (but only with small feed tube diameters). Nevertheless, when modeling flame front propagation through the feed system in real propulsion systems, the regression rate of liquid hydrazine flames must be known over the entire range of temperatures and pressures. This is important for scaled-up propulsion systems where tubing diameters may exceed 1 in. and more.

There are basically four methods for studying hydrazine decomposition flames: stabilization of a stationary vapor flame on a flame holder, photographic measurement of flame propagation in a closed vessel, liquid strand burning, and liquid droplet burning. Sometimes the term *hydrazine combustion* is used in a misleading fashion in reference to decomposition flames that do not involve an oxidizer and a fuel. In our terminology the term *combustion* is reserved for flames involving an oxidizer.

Experimental results of flame speed, quenching distance, critical pressure, and regression rate (“burning velocity”) of monopropellant hydrazine decomposition flames are discussed and compared in the following sections. In many cases the authors have attempted to relate the results of flame studies to kinetic data obtained at lower partial pressure in the non-flammable range. However, data that nicely agree with theoretical explanations at lower pressure fail to do so at higher pressures and temperatures.

The terminology and the difference between flame speed  $S_b$  and burning velocity  $S_v$  are explained by the fact that the flame speed is the speed at which the gases must flow if a stationary flame is to be obtained. The burning velocity relates to the combustion of the liquid, and, to avoid confusion, we prefer the term *regression rate*, which is borrowed from solid and hybrid rocket propellant combustion to describe this process.

Hydrazine decomposition flames were first observed during an investigation on the reaction of hydrazine with nitric oxide [1228]. It was one of the first compounds found to undergo controllable decomposition in the absence of an oxidizer.

Some additional information on hydrazine decomposition flames is contained in Section 8.1 on hydrazine safety. Sections 8.1.2 and 8.1.3 summarize information on the limits of propagation of hydrazine vapor decomposition at low pressures and with various diluents. Several of the papers discussed in the following sections discuss the pressure dependence of the flame speed  $S_b$  as an indication of the order of reaction  $n$ . The thermal theory of flame propagation predicts a relationship of

$$S_b \approx P^{\frac{(n-2)}{2}}$$

In a low-pressure regime, most investigators agree that the flame speed is independent of pressure. In the preceding equation, this would mean  $n = 2$ , a second-order reaction. Only at pressures above atmospheric pressure can an inverse square-root dependence be observed that is typical of a first-order reaction. Several purely analytical studies on flame propagation have endeavored to interpret the vast amount of experimental data, but this is not always easy. Experimental data on hydrazine flame speed are pressure-independent at low pressures [1204, 1378, 1379]. Thus, a second-order reaction mechanism was assumed to be controlling. Kinetics were given for a chain mechanism in which the  $\text{NH}_2$  radical is formed by a pseudo-unimolecular process, tending to first order at high pressures but second order at low pressures. The consequent set of flame equations could be solved using a chemical steady-state hypothesis. In this instance, however, the solution to the flame equation leaves both the flame speed and the overall chemical rate constant undetermined for hydrazine decomposition. Insertion of an experimental flame speed made it possible to obtain a value for this rate constant. It was also possible to calculate the second-order rate constant for the formation of activated  $\text{N}_2\text{H}_4$  radicals. The rate equation was

$$k_a = \sim 3 \times 10^{18} \exp(-60000/RT) \text{ cm}^3 \text{ mol}^{-1} \text{ s}^{-1}$$

The unusually high value for this constant suggested energy transfer to the N—N bond from many vibrational modes of  $\text{N}_2\text{H}_4$ . Re-examination of earlier data of Szwarc on the formation of  $\text{NH}_2$  radicals treated as a first-order process indicated that a second-order process may be implied from the data and, also, a value for

$$k_a = 10^{19} \exp(-60000/RT) \text{ cm}^3 \text{ mol}^{-1} \text{ s}^{-1}$$

may be deduced. Other authors provided only a review of existing flame reaction data [1380].

Several theories have been promoted for calculating and predicting flame speeds of monopropellant decomposition flames from the molecular and thermochemical properties of the reactant [1381–1384]. Usually far-reaching assumptions must be made to obtain all the input data to enter into such a computerized model, which often stands on shaky ground.

The flame speed of laminar decomposition flames has been described by an analytical model by first assuming that the steady-state assumption is justified for the concentration of radicals [1385]. Subsequently a model was developed for the computation of flame speed not including this assumption. Comparison of the results with experimental data from other authors indicated that a steady-state assumption was justified. Because the stoichiometry of hydrazine flames is simple in comparison to the combustion of pre-mixed reactants, hydrazine decomposition flames have frequently been used as model flames to validate various combustion models. For ambient pressure flames, good agreement was observed between calculated and measured values for laminar flame velocity (calculated: 1.84 m/s, measured: 1.85 m/s) and quenching distance (calculated: 0.5 mm, measured: 1.2 mm) of hydrazine decomposition flames in the absence of air [1386, 1387]. The ratio of flame velocity  $U_f$  to quenching distance  $D$  is proportional to the ratio of reaction rate  $w$  to initial fuel concentration  $A_0$ :

$$\frac{U_f}{D} \approx \frac{W}{A_0}$$

The general equations on laminar flame propagation in hydrogen, oxygen, and nitrogen mixtures are applicable to hydrazine combustion flames as well as decomposition flames [1388]. However, no numerical data were given for hydrazine flames. Some correlations allowed for the calculation of the burning velocity in pre-mixed laminar flames, including decomposition flames [1389].

An earlier flame model of the time-dependent laminar flame structure of decomposition flames, which was restricted to planar one-dimensional flames, was extended to the computation of cylindrical and spherical flames [1390]. Examples of flame speed and ignition energy for both planar and spherical flames were calculated, and an appreciable decrease in flame speed was computed when the flame radius was of the same order as the flame thickness. The theoretical model was then tested for hydrazine flames, and good agreement with other numerical results was obtained [1391]. A flame speed of 1.554 m/s in relation to the unburned hydrazine was calculated, compared to 1.54 m/s reported later [1392]. For a planar geometry, the model predicted that the reaction would complete within 0.4 mm from the origin of the flame front. The model calculated not only stationary flame speeds but also transient flame speeds during the ignition period. Thus, the model predicted that stationary flame speed would be achieved within 0.03 ms after ignition, certainly within a very short time. In addition to flame speeds and ignition transients, the model also calculated required ignition

energies. It specified the minimum size of a “hot gas pocket” serving as ignition center and the minimum energy required for ignition. If the pocket is too small, combustion does not propagate, and the flame becomes quenched after 80  $\mu$ s. If the pocket is twice as big, ignition occurs, and stationary conditions are attained within 40  $\mu$ s. The required minimum ignition energy is on the order of  $10^{-14}$  cal/cm<sup>2</sup> cross-sectional area of the hot gas bubble. It would be interesting to convert this number to the temperature required for ignition in a given volume in the absence of a surface. However, surface effects are difficult to eliminate.

Unsteady-state laminar flame theory was used to predict minimum ignition energies for hydrazine vapor and to predict flame speed, temperature profiles, and concentration profiles from ignition by spherical or elongated hot pockets to steady propagation of spherical flames [1393, 1394]. The time-dependent flame equations are solved in prolate spheroidal coordinates. It was shown that the minimum ignition energy was affected by the geometry of the ignition source and that the ignition energy passed through an absolute minimum as a function of the radius of the spark. The laminar flame velocity and minimum ignition energy calculations were repeated for hydrazine decomposition flames and resulted in profiles like those of Spalding and Bledjian. The ignition was assumed to occur by electric spark, and the electrode gap and spark temperature were among the several variables considered. Using the kinetics of two previous investigators, the vapor flame speed was calculated as a function of the distance from the point of initiation. For the starting conditions selected, the flame speed increased with distance from the point of ignition (e.g., a spark discharge or exploding wire) and did not become constant before it had traveled at least 1 cm. The flame speed approached the constant value asymptotically. The calculated flame speed of 1.52 m/s compared well with the 1.54 m/s reported earlier [1391] and the 1.554 m/s reported a few years later [1390]. Other reported flame speeds for hydrazine decomposition flames were 1.8 m/s on a 28-mm burner [620, 621].

The initiation and transient behavior of hydrazine flames depends on the initial energy in the hot pocket between the electrodes. If the energy is less than the threshold energy, the energy in the hot pocket is dissipated into the surrounding cool gas, and ignition does not occur. Given sufficient energy, the temperature of the hot pocket (assumed to be on the order of 3100 K) drops immediately after ignition and approaches the adiabatic flame temperature asymptotically. As the initial hot pocket expands, its velocity decreases since the pocket cools by expansion and by divergence, undergoes a minimum after approximately 80  $\mu$ s, and reaches the planar flame speed after more than 1 s. If one calculates the fate of hot pockets of identical initial temperature (e.g., 5000 K) and energy density as a function of pocket radius, one can identify a minimum hot pocket radius below which the flame dies down. Calculations showed this critical hot pocket diameter to be on the order of 0.03 mm, indeed a very small diameter. The theoretical minimum ignition energy for temperatures from 2500 to 10000 K ranged from  $1.2 \times 10^{-7}$  to  $1.8 \times 10^{-7}$  J, depending on the hot pocket radius (0.03–0.052 mm). Most spark discharges between electrodes do not create a spherical hot pocket, but an elon-

gated (“prolate spheroidal”) discharge. It was thus important to extend the theoretical considerations to non-spherical geometries as well. The prolate spheroidal pocket is less likely to result in ignition than a spherical pocket of equal energy because it has a greater surface area: volume ratio than the sphere and has a smaller radius than the sphere; the greater divergence again results in greater heat transfer and more rapid cooling than a sphere. It was found by modeling calculations that prolate spheroidal flames with a half-axis ratio of  $a/b \geq 10$  indeed die while a sphere of the same volume and energy will propagate a flame. However, when plotting minimum ignition energy as a function of  $a/b$ , the semi-axis ratio, a minimum at or near  $a/b = 2$  was noted. The curve ascended again to the value of a sphere ( $a = b$ ) at about  $a/b = 9$ . Because ignition depends on three variables (hot pocket radius, semi-axis ratio, and ignition energy), the boundary between ignition and failure to propagate can be described as a curved surface in a three-dimensional coordinate system. A better understanding of ignition phenomena and the importance of spark geometry may lead to the design of improved ignition devices, not so much for hydrazine, but for combustible vapor (gasoline)/air mixtures. Hydrazine decomposition flames were only used as an example to test the model because the mechanism is simple compared to that of other combustion reactions.

#### 4.9.1 Stationary Hydrazine Decomposition Flames Stabilized on Flame Holders

Whereas most other combustibles can be pre-mixed and burned in a Bunsen burner with a flame holder without special precautions, the attempt to stabilize a hydrazine monopropellant vapor decomposition flame requires special precautions to prevent flashback into the reservoir of hydrazine vapor. Accordingly, only a few experimenters have attacked this problem.

The flame speeds of hydrazine and hydrazine/water mixtures (60.0–97.2%  $\text{N}_2\text{H}_4$  in  $\text{H}_2\text{O}$ ) at 423 K (150 °C) and atmospheric pressure were measured by a burner method at atmospheric pressure [1210]. It was found that the flame reaction has the following stoichiometry:

It was assumed that the decomposition in the flame proceeded through a thermally activated first-order reaction, and on the basis of Szwarc’s results, an activation energy of 251 kJ/mol (60 kcal/mol) was suggested for the rate-determining step, believed to be the dissociation in amino radicals. However, as discussed in previous sections, this is not the true course of reaction. The all-glass experimental setup consisted of a hydrazine reservoir, a capillary flow meter, a vaporizer, a mixing section kept at 423 K, and a burner tube with an orifice. The same apparatus was also used to study hydrazine-oxygen and ammonia-oxygen flames (Section 4.14.1). Initially, some air was allowed to surround the diffusion flame, but some flames with high hydrazine concentrations did not need an air sheath and could be stabilized on the orifice without

external air supply. The orifice diameter was varied from 1.4 mm for 97%  $\text{N}_2\text{H}_4$  to 5 mm for 60.9%  $\text{N}_2\text{H}_4$ . The flames low in hydrazine could be stabilized only with a sheath of external diffusion combustion flame supported by air. The flame speed as a function of hydrazine concentration (remainder water) is shown in Figure 44.

**Figure 44:** Decomposition flame speeds in hydrazine-water vapor at 423 K. (Republished and modified from [1210], with permission of ©1951 Royal Society of Chemistry; permission conveyed through Copyright Clearance Center, Inc.)

The flame speed can be expressed as volume of vapor burned per unit flame surface (from photographs) per second. The volume of vapor was calculated at 423 K and 101 kPa (atmospheric pressure). Flame temperatures were also measured and were found to be between those calculated with or without ammonia decomposition, respectively. The speed of the self-decomposition front in hydrazine with more or less water vapor decreased with increasing water content [1395]. This thorough study gave some early fundamental insight into flame speeds, but no information on the pressure dependence of the decomposition flame speed was obtained. The pressure dependence was later investigated by a different method by measuring the regression rate of a liquid surface in a capillary tube (Section 4.10.1).

The measurements were later extended to the low-pressure range, where the burning velocity of 97% hydrazine at 393 K was determined at 4, 9.3, and 20 kPa (30, 70, and 150 mm Hg), respectively [1396]. The velocity remained constant over this range, close to 185 cm/s. It was very similar to the flame speed measured at atmospheric pressure. Besides flame speeds, emission spectra of the decomposition were recorded and compared to hydrazine and ammonia flames in oxygen and nitric oxide.

The flame speed of laminar flow flames seems to obey different reaction orders in different pressure regimes. It was found that below atmospheric pressure the flame speed was independent of pressure, which is indicative of a reaction of second order [1204]. A first-order reaction would predict an inverse square-root dependence on pressure. At higher pressure the flame speed was proportional to the reciprocal square root of the pressure, indicating an overall first-order reaction at higher pressures. As already discussed in Section 4.4.2, at lower pressure each collision leads to decomposition, whereas at higher pressure deactivating collisions are as frequent as activating collisions, and a stationary but small concentration of activated  $\text{N}_2\text{H}_4^*$  molecules prevails that decompose by a first-order reaction.

In a spectroscopic study of the hydrazine decomposition flame at 343, 353, and 363 K initial temperature and 1.86–3.46 kPa (14–26 mm Hg) pressure, only traces of excited NH radicals could be observed in absorption, indicating that the NH concentration in a hydrazine decomposition flame is significantly smaller than that in an oxygen-ammonia flame. The flame speed at 353 K and 1.86 kPa (14 mm Hg) was 152 cm/s. Besides emission and absorption spectra, mass spectra scans were also taken across the flame zone, showing  $\text{N}_2\text{H}_4$ ,  $\text{NH}_3$ ,  $\text{N}_2$ , and  $\text{H}_2$ . No  $\text{N}_2\text{H}_3$  could be observed with any of the methods, and therefore the authors prefer the mechanism

over the direct molecular decay

proposed by Husain and Norrish [521].

The concentration profile of  $\text{N}_2\text{H}_4$ ,  $\text{N}_2\text{H}_2$ , and  $\text{NH}_2$  in an orifice-stabilized hydrazine decomposition flame at 3.7 kPa (28 mm Hg) and 343 K was measured with a capillary quartz probe and a TOF mass spectrometer [1397]. The response factor of the mass spectrometer for diazene was not exactly known, but with some extrapolation and assumptions it was stated that the diazene concentration may be up to 0.7% of that of hydrazine prior to decomposition. This relatively high concentration would indicate that diazene plays an important role in the thermal and other modes of decomposition of hydrazine. The maximum of the  $\text{NH}_2$  and  $\text{N}_2\text{H}_2$  concentrations coincides with the zone in the flame where all hydrazine has disappeared (approximately 7 mm from the orifice at a flow velocity  $v_0 = 58$  cm/s).

Flame temperatures were measured in hydrazine/water mixtures in stationary decomposition flames and ranged from 1407 K at 60 mass-%  $\text{N}_2\text{H}_4$  to 1668 K at 82.5 mass-%  $\text{N}_2\text{H}_4$  [1215, 1398]. These temperatures are significantly higher than the theoretically possible maximum flame temperature at zero ammonia dissociation, and it may be assumed that some measurement error went undetected in this experiment.

Concentration profiles of  $\text{N}_2\text{H}_4$ ,  $\text{N}_2$ ,  $\text{H}_2$ , and  $\text{NH}_3$  across hydrazine decomposition flames at 1.86 kPa (14 mm Hg) were measured by withdrawing samples from an

8-cm-diameter burner into a mass spectrometer [561]. The initial temperature of the hydrazine vapor was 343, 353, and 363 K and had little effect on the concentration profiles. A maximum temperature of 1350 K was measured with a thermocouple, substantially lower than the 1700 K expected from theoretical calculations. With a linear flow rate of 97 cm/s, about 9 mol-% of the hydrazine decomposed within the first millimeter of the burner. For higher stream velocities, 6 mol-% decomposed at 120 cm/s and only 1% decomposed at 152 cm/s.

The ignition of a combustible gas stream by a hot jet was modeled using a boundary layer approximation of aerothermochemistry assuming a one-step unopposed global reaction following any order reaction kinetics with temperature dependence according to the Arrhenius rate law [1399]. The Prandtl and Schmidt numbers were assumed to be equal, so a similarity between the equation of energy and the diffusion equation exists, greatly simplifying the analysis. This model was applied to the thermal decomposition of azomethane and the thermal decomposition of hydrazine, with numerical calculations done for the first-order approximation. Graphs showed the temperature profile along the axis of the flow for different ratios of cold and hot gas. For each set of given temperatures of the cold combustible gas and the hot gas, there exists a minimum jet width below which ignition cannot take place. It was confirmed that if the width of the jet is large enough, then the ignition always takes place at some point of the stream, but if the width of the jet is small, whether or not the ignition takes place depends on the width of the jet and the temperature of the hot gas.

A detailed N/H reaction mechanism has been developed and validated by comparing modeling results with measurements of hydrazine pyrolysis in shock waves and in hydrazine decomposition flames at low and atmospheric pressures [1400]. The mechanism consisted of 51 reactions with 11 species. Rate constants for several decomposition reactions were estimated employing updated thermodynamic data. Analysis of the reactions abstracting an H atom from  $\text{NH}_3$ ,  $\text{NH}_2$ ,  $\text{NH}$ , and  $\text{N}_2\text{H}_4$  from 1000 to 2000 K demonstrated that the Evans-Polanyi correlation [1401] held true for the radicals H, NH, and  $\text{NH}_2$ . This should probably also be valid for the radicals N, NNH, and  $\text{N}_2\text{H}_3$ . Several rate constants were estimated under this assumption. No further adjustment of the mechanism was attempted. The computer model correctly reproduced the experimental rate of decomposition of hydrazine and the product distribution. The initial decomposition of  $\text{N}_2\text{H}_4$  into two  $\text{NH}_2$  radicals and the subsequent reaction  $\text{N}_2\text{H}_4 + \text{NH}_2 \rightarrow \text{NH}_3 + \text{N}_2\text{H}_3$  mainly govern the decomposition of hydrazine in dilute mixtures and together with the reaction  $\text{NH}_2 + \text{NH}_2 \rightarrow \text{N}_2\text{H}_2 + \text{H}_2$  control the propagation speed of a hydrazine flame. The computed speeds of such decomposition flames agreed well with low-pressure and atmospheric-pressure experiments for pure hydrazine and its mixtures with Ar,  $\text{N}_2$ ,  $\text{H}_2\text{O}$ , and  $\text{NH}_3$ . The measured concentration profiles of major and minor species in low-pressure hydrazine flames were well reproduced. A sensitivity analysis identified the critical reactions under these experimental conditions.

### 4.9.2 Stationary Flames in Porous Media

Rather than burning liquid hydrazine at the tip of an open capillary, an attempt was made to stabilize liquid hydrazine decomposition in inert porous media. One such experiment used either crushed silicon carbide granules or bundles of parallel quartz rods of equal diameter in a 27-mm-ID, 250-mm-length quartz tube [1402, 1403]. Two granule sizes (1.0–1.2 and 2.0–2.5 mm) and several quartz rod diameters (1 to 5 mm) were tested. Liquid hydrazine was pushed in from one end of the tube and decomposition products passed through a section of the porous bed before leaving the tube at the opposite end. This method of combustion study is also called liquid infiltration combustion. The decomposition was initiated before starting hydrazine feed pump operation and a decomposition front propagated into the porous bed. The flow rate of hydrazine delivered by the feed pump was then adjusted such that the flame front remained stationary. The wave speed and the flow rate of the infiltrating fluid were similar, both on the order of 0.1 to 0.3 mm/s. Decomposition occurred in a stable planar reaction front at atmospheric pressure. Due to the high heat of evaporation, the pre-heat zone of hydrazine in the porous medium was wider than with other monopropellants. The axial temperature profile showed a sharp bend at the boiling point of hydrazine. One must remember that this was not a truly one-dimensional process, and capillary forces caused liquid to flow radially in addition to axially. The burning velocity decreased with the liquid feed velocity and the flame quenched below a lower limit. The burning velocity and the length of the gas-liquid zone decreased with increasing opening size of the porous medium (coarser granules or wider quartz rods).

Modeling the strand burning of liquid monopropellants in a capillary tube is also called filtration burning in the Russian literature because it simplifies the burning of a monopropellant in a porous medium or tube by looking at only one strand of liquid. Monopropellant burning in a porous medium (a packed bed of inert granules or rods or ceramic foam) was the original burning mode, which was called filtration combustion or filtration burning. A better description of the process would be infiltration combustion or infiltration burning. Filtration combustion of a monopropellant liquid is like filtration gas combustion in a low-velocity regime, which occurs under strong thermal interaction between the gas and the porous medium. A one-dimensional two-temperature model for the filtration combustion of liquid monopropellants was used to analyze the filtration combustion of liquid hydrazine in narrow tubes [1404, 1405]. This model described qualitatively the behavior of steady-state combustion waves of a liquid monofuel infiltrated into a porous medium or a capillary tube. A comparison of experimental data on the combustion of hydrazine in a porous medium and in narrow (5-mm quartz) tubes with calculations by the model showed that the model provided an adequate qualitative description of the infiltration combustion of liquid monopropellants. In a continuation of this study, two steady-state regimes were found [1406]. In regime I, the dominant mechanism of heat transfer from the combustion products in the pre-flame zone

was heat conduction in the gas, and in regime II, the dominant mechanism of heat transfer was interfacial convective heat transfer and heat conduction in the solid phase, the wall of the tube. Calculations using this model were in good agreement with experimental data on the combustion of liquid hydrazine in narrow tubes [1407].

#### 4.9.3 Hydrazine Vapor Decomposition Flames in Closed Vessels

The decomposition of hydrazine vapor was first studied using 3- and 1.5-cm-diameter Pyrex tubes 10 cm in length [1228]. Ignition was achieved by an electric arc across tungsten electrodes. The tube was kept at 373 K to prevent hydrazine condensation. The lower pressure limit depended on the diameter of the tube. Thus, with reaction vessels with diameters of 1.5 and 3.0 cm, the lower explosion limits were reached at hydrazine pressures of 6.64 and 4.65 kPa (50 and 35 mm Hg), respectively. Later investigations in a 118-mL, 2.54-cm (1-in.) Pyrex tube found hydrazine decomposition flame propagation with spark ignition at even lower pressures [1408]. The minimum pressure for the spark ignition of hydrazine vapor was 1.6 kPa (12 mm Hg) at a bath temperature of 302 K (29 °C). This was somewhat lower than the value of 4.65 kPa (35 mm Hg) given by [1228].

The study of hydrazine decomposition flames in closed vessels requires the use of fast recording instrumentation, such as high-speed-film cameras and oscilloscopes. The phenomena are steady only for a short time, and after the flame front has propagated for a short length, the effect of the diffusion of decomposition products may become noticeable. Even though the initial temperature and pressure can be closely controlled, pressure will increase as soon as the reaction starts, and temperature will increase as a result of adiabatic compression. Thus, in a vessel diameter  $R$ , only the initial flame path up to  $0.3R$  is usually taken for calculating the flame speed.

The propagation and stability of hydrazine decomposition flames were studied in a closed vessel and by the liquid strand method (see following section) [1409–1411]. A fourfold increase in pressure from 2.66 to 10.6 kPa (from 20 to 80 mm Hg) produced little variation in the flame speed of pure hydrazine. At 6.64 kPa (50 mm Hg) and 393 K the flame speed relative to the unburned gas was 117 cm/s, which agreed with a previous measurement of 200 cm/s at 423 K and atmospheric pressure, that reported by Murray and Hall [1210].

The addition of diluents (helium, argon, hydrogen, nitrogen, ammonia) decreased the speed of the decomposition flame. The effectiveness of decreasing the flame speed increased in the order listed previously in parentheses and (except for He) seems to relate to the heat capacity of these gases. This agrees with the conclusions drawn by others on the effect of diluent gases on the autodecomposition pressure limit of hydrazine [1216]. Because some secondary decomposition of ammonia may have occurred in the closed vessel after the flame front had propagated all the way through

the chamber, the gas composition was slightly different from that expected for the following equation:

the actual composition being

One issue addressed by numerous investigators was to determine the cause of the relatively weak pressure dependence of the flame speed. It can be explained if the rate is determined by bimolecular activation, not by unimolecular decomposition.

The burning rate results of other authors were subjected to a critical review and attempts were made to fit them to a one-center chain reaction model that had been programmed on a computer in an effort to predict the effect of pressure on the speed of the hydrazine decomposition flame [1412]. Data were calculated from 1300 to 1900 K and 10 kPa to 10 MPa (0.1–100 atm). Although numerical results did not fully agree with experimental data, the computer model was at least able to predict the trends. The temperature coefficient of the flame speed was found to be independent of the assumptions made regarding the chain-terminating reaction. This was believed to be due to the fact that the rate of chain termination is small compared to the rate of chain propagation and that the activation energies of both are small compared to that of the initiating reaction (293 kJ/mol). Experimental results indicated that the temperature coefficient of flame speed corresponded to an overall activation energy of little more than half that of the initiating step (at that time still believed to be the decomposition of hydrazine into  $\text{NH}_2$  radicals) [1210, 1411]. The pressure dependence predicted by the computer for lower flame temperatures at pressures above atmospheric was very unusual. The calculated reaction order varied from 1.4 near atmospheric to 0.7 at a pressure of 1.5 MPa and increasing again to 1.0 at 10 MPa. No experimental data for vapor-phase flames are available to check these predictions. On the other hand, the authors conclude that the propagation reaction is almost certainly second order at all times. For the termination reaction they assumed a reaction second order in radical concentration but third order in total pressure. This is required for the assumed three-body recombination of free radicals, but the reaction may become second order at very high pressures when the time between collisions is shorter than the half-life time of an excited molecule. The explosive decomposition of anhydrous hydrazine vapor can be initiated with an electrostatic discharge (ESD) [1398].

Besides spark-ignited decomposition flames, thermally ignited spontaneous decomposition flames or, depending on the confinement conditions, explosions in closed vessels have also been studied [1413]. If hydrazine vapor is expanded from a reservoir into a hot, evacuated vessel, it will ignite as soon as its pressure exceeds the critical spontaneous ignition pressure for the given temperature of the vessel. Spontaneous ignition pressure results obtained with a quartz cylinder 3.7 cm in diameter  $\times$  250 cm<sup>3</sup> in volume  $\times$  300 cm<sup>2</sup> in surface area are shown in Figure 45.

**Figure 45:** Explosion limit of hydrazine. (Reprinted and modified from [1414], with permission from ©1962 Elsevier; permission conveyed through RightsLink.)

At sufficiently high pressures, the ignition of pure hydrazine was seen as a bright yellow flash with an induction period of less than 1 s. As shown in Figure 45, the initial pressure required for ignition decreased from 8.64 to 1.06 kPa (from 65 to 8 mm Hg) as the temperature was increased from 853 to 1083 K. Dilution (1:1 ratio) with helium or argon had only a negligible effect on the pressure limit (as long as only the partial pressure of hydrazine in the gas mixture is plotted). Helium increased and argon diminished the difficulty of ignition.

It is interesting to note that under the same experimental conditions, UDMH vapor would undergo spontaneous self-decomposition at lower initial temperatures than hydrazine, for example, 703 K at 8 kPa (60 mm Hg) as opposed to 873 K for hydrazine at the same pressure (Table 58).

**Table 58:** Approximate autodecomposition temperatures.

| Compound  | Approximate autodecomposition temperature, K |      |                         |      |
|-----------|----------------------------------------------|------|-------------------------|------|
|           | Partial pressures kPa                        |      | Partial pressure, mm Hg |      |
|           | 8                                            | 0.8  | 60                      | 6    |
| Hydrazine | 873                                          | 1073 | 873                     | 1073 |
| UDMH      | 703                                          | 788  | 703                     | 788  |

Data source: [1413]

A similar closed vessel apparatus, also filled by fast admission of hydrazine vapor to a pre-evacuated vessel, was used to study the borderline conditions for the initiation of hydrazine vapor explosions [1414]. Instead of igniting with an electric arc, the entire vessel was pre-heated to the ignition temperature. The admitted vapor usually warmed up to equilibrium temperature in 10–40 ms, depending on the size of the vessel. This was probably due to the convective heating of the incoming vapor stream and adiabatic compression of the first portion of vapor to enter the flask, the same effect that caused some interference in Gray's test. Instead of measuring flame speed, the pressure rise inside the vessel was recorded with a high-response pressure transducer and an oscilloscope. The explosion limit of hydrazine as a function of pressure and temperature is shown in Figure 45 for two different size vessels in comparison to data obtained by Gray [1411].

It was stated that whereas hydrazine decomposition does not show the usual properties of branched-chain explosions (multiple limits, extremely slow reaction below the limit, dependence on surface), it does not agree with the theory of thermal explosion, either. The addition of hydrogen or helium did not cause the change in the explosion limit predicted from their respective thermal conductivity. Ammonia lowers the explosion limit pressure  $p^*$  slightly. The amount of decomposition during the induction period was higher than predicted. The pressure rise during the induction period preceding the explosion was 15–20%. The stoichiometry of decomposition below and above  $p^*$  was markedly different. Below  $p^*$  it could be represented by

Above  $3p^*$  the yield of ammonia levels off:

Laminar and turbulent hydrazine decomposition flames in a closed vessel (70-mm diameter) were studied at 383 K and 80 kPa (600 mm Hg) [1415]. The combustion bomb had windows for schlieren cinematography and a pair of spark electrodes for initiating the decomposition. The flame speed was varied by dilution with nitrogen or water vapor and plotted as a function of the theoretical flame temperature  $T_h$ . It was noted that a significant fraction of hydrazine would decompose prematurely when hot hy-

drazine vapor was admitted to a hot, evacuated vessel. Apparently, some of the hydrazine molecules that were already heated close to the borderline of self-propagation reached high velocities on expansion into a vacuum as a molecular jet and the resulting increase in kinetic temperature caused them to decompose. When nitrogen was admitted first, followed by hydrazine vapor, only negligible decomposition was observed.

The authors noted that the difference in flame speed measured by the closed bomb and open burner flame method [1210] cannot be explained by the difference in initial temperature alone. The temperature dependence of the rate of laminar flame burning can be represented by the formula

$$S_B \propto T_0 T_h^{2.7} (T_h - T_0)^{-1.5} e^{\frac{-E}{2RT_h}}$$

where  $T_h$  is the adiabatic flame temperature (1904 K according to [1415]),  $T_0$  is the initial temperature in K, and  $E$  is the activation energy (generally assumed to be 37 kcal/mol). The ratio of flame speeds calculated with this equation for 423 and 335 K initial temperature, respectively, was 1.38, whereas the measured ratio was 1.7. In trying to explain this discrepancy, Karpov and Sokolik pointed out that a certain degree of turbulence cannot be avoided in a burner stabilized flame. They then determined flame speeds in a closed bomb with and without agitation by stirrers. Very similar energies of activation in the preceding equation were obtained for both types of flame, but the turbulent flame speed was higher than the laminar flame speed. In addition to the temperature dependence, the pressure dependence of laminar and turbulent flame speeds was measured in that study. It was shown that, in agreement with earlier results [1411], the order of reaction for both laminar and turbulent flames was approximately 2, resulting in an overall independence of flame speed from hydrazine pressure in the range 11.9–42.5 kPa (90–320 mm Hg). Whereas a thermal model was assumed to treat the steady laminar flame, pulsating combustion and periodic mixing of burned and unburned gas were assumed for turbulent flame propagation.

The effect of isotopic substitution on the decomposition flame speed of hydrazine was studied using the same closed-bomb technique previously described [1154]. The comparison was extended by measuring flame speeds for binary mixtures containing inert diluents. Increasing amounts of two diluents, argon and nitrogen, were added to a fixed partial pressure (6.7 kPa = 50.2 mm Hg) of  $N_2D_4$ , and flame speed was measured over the entire flammability range. The effect of the added diluents was to decrease the flame speed with increasing partial pressure of diluent and to extinguish the flame when the concentration of diluent exceeded ca. 50%. The effective activation energy was estimated from the dependence of flame speed on temperature for diluted mixtures. It was estimated to be  $146 \pm 8$  kJ/mol ( $35 \pm 2$  kcal/mol), based on

calculated values of adiabatic flame temperature and thermal conductivity, assuming a stoichiometry identical to that for  $\text{N}_2\text{H}_4$  decomposition. A large isotope effect of flame speed was apparent when the results were compared directly with those of a previous investigation of the  $\text{N}_2\text{H}_4$  flame, obtained in the same apparatus and under the same initial conditions. The speed of the hydrazine decomposition flame was halved when deuterium was substituted for hydrogen. The flame speeds relative to the burned gas were determined by schlieren photography. Flame speeds for pure  $\text{N}_2\text{D}_4$  were measured at an initial temperature of 335 K in the pressure range 2.6–9.3 kPa (20–70 mm Hg). In this pressure range the flame speed was virtually independent of pressure, indicating that the overall reaction was of second order [1316, 1411]. Substitution of deuterium for hydrogen in hydrazine has a very pronounced effect on the decomposition mechanism. The flame speed of the hydrazine decomposition flame is halved when deuterium is substituted for hydrogen. At least three parameters affecting flame speed are believed to be responsible for this change: transport properties, equilibrium thermodynamics, and kinetic factors. Isotopic changes in thermal conductivity contribute by a factor of 1.1 to the total effect, adiabatic theoretical flame temperature is off by a factor of 1.3–1.5, and kinetic isotope effects have the most pronounced effect,  $k_{\text{H}}:k_{\text{D}} = 1.5$ . This investigation was stimulated by the decades-old question as to whether the decomposition of hydrazine proceeds by way of a unimolecular or a radical mechanism. This question was already extensively discussed in Section 4.4.1 in view of recent shock-tube results. Although these results indicate a unimolecular mechanism at high pressures, the possibility of a radical mechanism, such as the one proposed by Adams and Stocks in 1953 [1249] and confirmed by many other investigators, still exists.

The most surprising effect of isotopic substitution was a 50% reduction of flame velocity when deuterium was substituted for hydrogen in hydrazine [1154]. For example, at an initial pressure of 6.67 kPa (50.2 mm Hg), the flame speed for  $\text{N}_2\text{H}_4$  decomposition was 1330 cm/s, whereas for  $\text{N}_2\text{D}_4$  it was 683 cm/s. With the use of a standard enthalpy of formation of 79 kJ/mol (+18.90 kcal/mol) for  $\text{N}_2\text{D}_4$  vapor, an adiabatic flame temperature of 1805 K was calculated compared to 1904 K for  $\text{N}_2\text{H}_4$ . Besides flame temperature, thermal conductivity is also lower for  $\text{N}_2\text{D}_4$  vapor than for  $\text{N}_2\text{H}_4$  vapor,  $712 \times 10^{-6} \text{ cal cm}^{-1} \text{ s}^{-1} \text{ K}^{-1}$ , compared to  $870 \times 10^{-6} \text{ cal cm}^{-1} \text{ s}^{-1} \text{ K}^{-1}$ . All these differences contribute to the large isotope effect. The isotope effect in the hydrazine decomposition flame is higher than in any other flame reaction studied to date. The activation energy of the  $\text{N}_2\text{D}_4$  decomposition was found to be essentially identical to that of  $\text{N}_2\text{H}_4$  decomposition over the range studied, 146 kJ/mol (35 kcal/mol) in both cases. The interpretation of kinetic data led the authors to the conclusion that neither a radical nor a unimolecular reaction is clearly supported by the isotope flame speed results. It was suggested to perform a shock-tube study to obtain some more definite rate data.

#### 4.10 Liquid Strand Decomposition in Absence of Oxygen

Of all methods for studying hydrazine decomposition flames, the “burning” of liquid strands in tubes is most easy to perform safely. The term strand burning has been inherited from solid propellants where this technique is extensively used to determine linear burning rates. However, the flame speed in the vapor phase is in reality higher than the regression rate of the liquid because the vapor and the liquid surface are moving in opposite directions, and the volume of the vapor is many times that of the liquid from which it originates. Heat-transfer phenomena between the flame front and the vaporizing liquid may affect the regression rate more than kinetic changes in the flame front would. Also, the flame front has a different shape and different surface area than the liquid-vapor interface. At 1 g on the surface of Earth, the flame front is hardly ever disc shaped, which would be the easiest shape to treat mathematically. Wall effects and gravity cause it to assume dish and ogive shapes. Strand burning phenomena have been studied for many monopropellant candidates, in particular those containing organic nitro compounds and nitrate esters. Some of the same experimental techniques developed during the 1950s were later applied to hydrazine. It was one of the safety advantages of hydrazine that under normal operating conditions it does not have a tendency to strand burn, which would be highly undesirable if strand burning propagated in a rocket from the combustion chamber through the injector through the valve and into the propellant reservoir (as has happened in many instances with nitro and nitrate compounds). However, if hydrazine were to be used in a valveless design of an on-demand gas generator, there may be problems with burn-back at higher pressures.

The walls exert a quenching effect on the flame, and some heat is lost to the walls. This quenching would be desirable for arresting unwanted propagation in flight applications, but it is undesirable for academic lab studies of burn rates. Lab tests have been conducted with heated capillary walls to compensate the heat loss. Attempts have also been made to calculate the quenching effect and correct the results for the expected heat loss. Nevertheless, despite all shortcomings of the capillary tube method for measuring burn rates, some interesting results can be obtained by this simple method, which is certainly not quite as dangerous as the Bunsen burner method, which involves large amounts of hydrazine vapor. The strand burning method has also been used to study the hydrazine combustion in oxidizing atmospheres.

##### 4.10.1 Monopropellant Strand Burning of Liquid Hydrazine (in Absence of Oxidizers)

The rate of monopropellant burning of hydrazine has been measured for a wide range of pressures (101–3500 kPa = 1–35 atm) and water dilutions [1249]. The liquid hydrazine is assumed to have been at room temperature, but no temperature measurements were given and there was no effort to maintain constant hydrazine temperatures. The regression rate was measured by observing the regression of

the liquid surface in a capillary tube. First, the effect of the tube diameter on the regression rate was studied in order to select a proper tube geometry for the experiment. It was found that the rate initially decreased and then leveled off beyond a 5-mm diameter. Therefore, most subsequent experiments used a 5-mm-diameter graduated tube. The rate of regression increased with increasing pressure, following roughly a square-root proportionality up to 1 MPa (10 atm), and then becoming independent of pressure above 1 MPa. Surprisingly, above a certain initial nitrogen pressure (4.4 MPa), the liquid will no longer ignite from a hot wire, or, if the pressure is raised during the burning experiment, the flame will extinguish at the same limit pressure. Apparently increased nitrogen dilution restricts flame propagation. For 98.9% hydrazine in a 5-mm tube, the regression rate increased from 0.28 mm/s at atmospheric pressure to 0.77 mm/s at 810 kPa (8 atm) and leveled off at this pressure until extinction occurred above 4.24 MPa (42 atm). As expected, water addition decreased the regression rate. The slope of the burn rate =  $f$  (concentration) curve becomes steeper with increasing water content [1386, 1387]. Strand burning rates as a function of pressure can be predicted for several hydrazine/water mixtures using the model developed by Gerstein [1387]. The agreement between experimental and calculated data for 98.9% hydrazine in a 5-mm tube at pressures of 20–1500 kPa was quite good. Between 20 and 1500 kPa, the regression rate of 98.9% hydrazine increased from 0.005 to 0.08 cm/s. The quenching distance was also calculated (0.05 cm) and measured (0.12 cm). Several of the conclusions drawn by early investigators [1249] in the interpretation of their own results and those of Murray and Hall [1210] turned out to be incorrect due to a lack of fundamental information on hydrazine decomposition that became available only during the following decades.

Gray and co-workers [1411] as well as Hall and Wolfhard [1396] extended the range of liquid hydrazine strand burning investigations into the region of low pressures. A lower limit extinction pressure was detected that is a counterpart to the high-pressure (dilution) extinction. The lower pressure limit for the propagation of the decomposition flame was measured in four tubes with diameters increasing from 3 to 10 mm. Also, the hydrazine concentration was varied from 91.4 to 97.7%  $\text{N}_2\text{H}_4$  (remainder water). The extinction pressure increased with tube diameter and hydrazine concentration. For a given tube, for example, 5 mm, the regression rate increased with pressure, whereas at constant pressure the rate was smaller in tubes of larger diameter. Combining the results of [1249] and [1411], the limits of stability and regression rate of liquid hydrazine decomposing in a 5-mm-diameter glass tube are illustrated in Figure 46 as a function of pressure and hydrazine concentration. In interpreting this graph, one must keep in mind that at pressures above atmospheric the increased pressure is by nitrogen pressurization, not true undiluted hydrazine pressure. The upper limit of propagation would not exist in a nitrogen-free system. The initial temperature of the hydrazine was ambient temperature, but some heat was transferred to the liquid from the tube as the flame traveled down the tube.

**Figure 46:** Limits of stability and regression rates of decomposition flame of liquid hydrazine. (Reprinted and modified from [1411], with permission from ©1957 Elsevier; permission conveyed through RightsLink.)

The law of mass conservation dictates the relationship for stable combustion

$$u_0 \rho_0 = u_c \rho_c$$

where  $u_0$  is the regression rate of the liquid surface,  $\rho_0$  is the density of the burning liquid,  $u_c$  is the velocity of the decomposition products relative to the flame front, and  $\rho_c$  is the density of the decomposition products. In a gravity field the buoyancy of the hot gases may result in the detachment of a bubble of hot gases from the surface of the burning liquid and the influx of cold gas from the sides. This phenomenon is called flame front separation. When the velocity of convective rise of the bubble exceeds the velocity of the decomposition products  $u_c$ , the combustion becomes unstable. The critical diameter and pressure above which the hydrazine flame is extinguished were calculated assuming a convective mechanism and compared with experimental values for different hydrazine concentrations in Table 59.

**Table 59:** Regression rate and critical pressure of hydrazine decomposition flame.

Data source: [1416]

At pressures above 1 MPa the reproducibility of the results became worse, and the average values of the burning rate tended to be independent of pressure. Hydrazine could not be ignited above a certain critical pressure  $p_{cr}$ , which could be predicted and calculated from the properties of the decomposition products.

Liquid hydrazine was fed from a reservoir through a peristaltic pump to a 5-mm-ID vertical quartz capillary with 1.1-mm walls in a decomposition chamber at 0.1 MPa and 293 K [1417, 1418]. Under normal conditions with a flow velocity of 5.9 mm/s, the regression rate was 4.8 mm/s in a tube with 1.1-mm walls. The slope of the regression rate  $u_0$  vs. fluid flow velocity  $v_0$  depends on the wall thickness and increased with increasing wall thickness. At low flow velocities ( $\leq 0.3$  mm/s) the combustion was steady, but at high flow velocities ( $\geq 0.8$  mm/s) it became turbulent and droplets were thrown out of the liquid interface into the space above. For a flow velocity of 0.6 mm/s, the flame front could be stabilized at the tip of the capillary, and the regression rate  $u$  of the interface was seemingly zero. In the transition regime bubbles began to appear at the interface. The regression rate as a function of wall thickness curves showed maxima at a wall thickness of  $\sim 1$  mm, in particular for flow velocities on the order of 0.2 mm/s. The curves all converged at a regression rate of 0.3 mm/s for very thin tubes. The quartz tube played an important role in the heat transfer between the decomposition front and the liquid. Under some conditions the quartz tube became bright red hot and its radiation accentuated its role as a flame holder.

When liquid hydrazine decomposed in glass tubes, an abrupt increase in the regression rate was observed as the pressure was increased [1419]. For 100% hydrazine in a 5.6-mm-diameter tube the regression rate increased from 0.02 cm/s at 101 kPa slowly and leveled off at 0.09 cm/s at 1.21 MPa (12 atm), until at 1.414 MPa (14 atm) a sudden increase to more than 0.2 cm/s was observed. No change in the smoothness of burning or any other parameter could be correlated with this discontinuity. The pressure at which this abrupt change occurs was called the break pressure, and its dependence on tube diameter and hydrazine concentration has been studied [1205, 1420]. The break pressure decreased linearly from 1.414 MPa (14 atm) to 0.4 MPa (4 atm) if the tube diameter was increased from 5.6 to 12.7 mm. The break pressure increased with decreasing hydrazine concentration.

The luminosity and gas temperature of the decomposition flame were also measured but did not change as abruptly as the regression rate. Therefore, there are no

changes in mechanism that could explain this phenomenon, and it was suggested that physical and not kinetic factors caused the change of reaction/regression rate. There is a certain risk in overinterpreting the liquid strand burning rate data. Adams and Stocks [1249] tacitly assumed that a first-order gas-phase reaction controlled the burning rate, even though some deviation at the high-pressure end was obvious. A study of the burning of hydrazine between 101 and 1818 kPa (1–18 atm) found a one-third power dependence of regression rate on pressure [1409]. Gerstein interpreted the results of previous investigators and proposed a model equation [1386, 1387]. It was later concluded that the regression rate of liquid hydrazine is controlled primarily by a second-order reaction in the gas phase and that in certain pressure ranges (depending on the tube diameter and the concentration of the liquid) the regression rate is limited by an evaporation rate [1419]. A good correlation could be obtained with a burning rate/pressure dependence equation originally developed for solid propellants.

If nitrohydrazines were stable (they are not), they would have very high burning rates, faster than those of HN or ammonium dinitramide (ADN) [1421].

#### 4.10.2 Effect of Additives on Monopropellant Strand Burning of Liquid Hydrazine

In a study of the effect of additives on the strand burning rate of liquid hydrazine in a nitrogen atmosphere, it was found that the addition of water or other additives had two effects: **(1)** The regression rate at any pressure was lowered and **(2)** the pressure at which the regression rate increased abruptly was increased [1422]. One percent by volume solutions of the following additives were tested (listed in the order of increasing effect on regression rate): MMH, ethanol, ethylene diamine, *n*-amylamine, *tert*-butanol, pyridine, and *n*-butanol. Whereas MMH had no measurable effect, the effect of the other additives seemed to increase with the number of carbon atoms.

The strand burning characteristics of hydrazine were measured under both steady-state and imposed oscillatory conditions [1254]. Strand burning rates, liquid temperature distributions, and surface temperature were measured as a function of pressure in the range of 32 kPa to 4.2 MPa (0.32–42 atm). It was found that at sub-atmospheric pressures the burning rate varied as the square root of pressure, whereas for pressures greater than atmospheric the burning rate was a linear function of pressure. Attempts were made to explain this behavior by setting up a theoretical model and assuming a reaction order of 1 at sub-atmospheric and an order of 2 for super-atmospheric pressures. An oscillatory burning modification of the steady-state strand burning apparatus was built, and measurements in the oscillating mode were taken. Theory and experiment were found to be in good agreement (100–1000 kPa) if the hydrazine decomposition reaction was assumed to be second order with an activation energy of 167 kJ/mol (40 kcal/mol). The results showed an increase in the response of the combustion process to the same extent as interaction occurred with transient liquid-phase effects. There was a frequency range where the combustion process exerts enough amplifying power to drive a resonant oscillating system with

subsequent combustion instability. It is not known what implications this might have for monopropellant thrusters because most decomposition there occurs on the surface of catalysts rather than on the surface of liquid strands or droplets.

In addition to strand burning rates, the flame temperature and composition of decomposition products were also determined over a wide range of pressures (101–2626 kPa = 14.7–382 psia) [1423]. A remotely actuated sampling probe was inserted into the flame front for a very short time to withdraw gases for continuous mass spectrometer analysis. The probe dwelled in the flame only long enough to draw a sample, yet not too long to suffer damage from the high temperature. The linear regression rate in a 10.8-mm tube increased from 0.04 cm/s at atmospheric pressure to 0.32 cm/s at 2.6 MPa. The overall stoichiometry of decomposition products could be represented by

The ammonia concentration increased with increasing pressure from 1.023 to 1.095 mol of  $\text{NH}_3$  formed per mol of  $\text{N}_2\text{H}_4$  decomposed. The linear regression rate agreed closely with molar mass combustion rates (in units of  $\text{g mol cm}^{-2} \text{s}^{-1}$ ) predicted using the Belyaev-Zeldovich equation

$$u = \frac{RT_c^2}{QE} \sqrt{2\lambda\rho kc}$$

where  $u$  is the mass combustion rate ( $\text{g cm}^{-2} \text{s}^{-1}$ ),  $c$  the heat capacity ( $\text{cal g}^{-1} \text{K}^{-1}$ ),  $Q$  the enthalpy of reaction corrected for phase changes ( $\text{cal/g}$ ),  $k$  the rate constant of the reaction at combustion temperature ( $\text{s}^{-1}$ ),  $\lambda$  the thermal conductivity of vapor ( $\text{cal cm}^{-1} \text{s}^{-1} \text{K}^{-1}$ ),  $E$  the activation energy ( $\text{cal/mol}$ ),  $T_c$  the combustion temperature (K),  $\rho$  the gas density ( $\text{g/cm}^3$ ), and  $R$  the gas constant. The gas constant  $R$  is available in many units of measurement, e.g.,  $1.98 \text{ cal mol}^{-1} \text{K}^{-1}$ , and needs to be selected so the equation will balance. The liquid strand burning technique is useful for studying oxidizer-free decomposition flames and oxidation flames alike. The effects of additives, temperature, and oxidizing atmosphere on the combustion of liquid hydrazine in a paper straw tube were studied [1424]. The strand burning rate of hydrazine/water mixtures increased from 0.018 to 0.040 cm/s as the hydrazine content increased from 85 to 100 mass-%. Lead nitrate, potassium permanganate, nickel chloride, chromium chloride, and thallium(I) chloride were tested as burning rate catalysts. Their activity decreased in the previously given order, with lead nitrate being the most active catalyst, increasing the burning rate  $r$  to 0.062 cm/s. Combustion in oxygen, nitrogen dioxide, or nitric oxide occurred faster than in air, whereas nitrous oxide retarded combustion. When the logarithm of  $r$  was plotted against  $1/T$ , a straight line was obtained. An energy of activation was calculated from the slope of the line and was found to be only 12.5 kJ/mol (3 kcal/mol). The maximum temperature of the hydrazine-air flame measured was 1360 K.

#### 4.10.3 Effect of Hydrazinium Salts on Strand Burning of Liquid Hydrazine

Solutions of hydrazinium(1+) nitrate (HN) in hydrazine and water have been considered propellants for liquid propellant guns along with other monopropellants. The combustion of hydrazine/hydrazinium nitrate solutions in the breech of a liquid propellant gun would be without the aid of a catalyst. A mixture of 30% HN, 65% hydrazine, and 5% water was tested in 37-mm guns and as strand burners in a pressurized bomb [1425]. In 3.8- and 6-mm-diameter strands, the strand burning rate of this mixture at 200 MPa (29 kpsi) was approximately 25 cm/s. However, in a gun barrel, a liquid charge 19 cm long was combusted at the same pressure within 1 ms. This indicated that the burning surface must have been increased by internal droplet breakup (Taylor instability and Helmholtz mixing) to more than 6000 cm<sup>2</sup>. Unfortunately, the hydrazine-HN propellant and all other liquid gun propellants tested suffered from combustion variations, thus causing an intolerably wide scatter of muzzle velocities and projectile ballistics. A similar mixture consisting of 75% HN, 20% hydrazine, and 5% water had previously been tested without the desired success [1426]. These tests indicated that even for such high HN concentrations, stable combustion could not be sustained at pressures below 13 MPa.

#### 4.11 Decomposition of Hydrazine Droplets in an Atmosphere of Decomposition Products

The decomposition combustion of droplets is a process of great industrial importance. A review of 216 references on the combustion of droplets of liquid fuels and monopropellants summarized the theoretical background accumulated prior to 1973 [1427]. Decomposition and combustion flames with monopropellant droplets stand out with respect to the mechanisms involved and the combustion velocities. The study of monopropellant and, in particular, hydrazine droplet decomposition burning has contributed significantly to the understanding of droplet combustion in general.

Hydrazine was chosen as one of the fuels investigated in both monopropellant and oxidizing atmosphere droplet combustion studies [1428–1430]. The solving of the system of three nonlinear differential equations describing burning rate as a function of droplet diameter and pressure required a significant mathematical effort that cannot be repeated here. The agreement of calculated data with experimental results was satisfactory; however, combustion of monopropellant droplets in an absolutely inert atmosphere was not achieved. The droplets were suspended from a quartz capillary and were smaller than the droplets used by Rosser and Peskin [1431, 1432]. The latter authors used porous alumina spheres of various diameters (3–13 mm) to support hydrazine drops. The reaction vessel was a 15-cm (6-in.)-diameter Pyrex tube. The hydrazine was fed to the porous alumina sphere by a linear drive motor from a syringe and ignited by an electric arc. During burning, a gas stream of selected composition

flowed upward and past the burning liquid. The feed rate was adjusted so that the sphere was uniformly wetted but would not drip or run dry. No decomposition occurred inside the alumina sphere, and the measured temperature inside a drop of hydrazine was only 367 K. The mass burning rate was proportional to the square of the drop diameter, rather than the first power of the diameter, as for drop diffusion flames. The mass burning rate was proportional to the radius only for very low reaction rates or in the evaporative limit. For high reaction rates, the mass burning rate was proportional to the square of the radius. The ability to maintain decomposition flames was found to be dependent on the purity of the hydrazine. Aniline was identified as an inhibitor. Hydrazine with 1.5 mass-% aniline would not sustain a pure decomposition flame at atmospheric pressure with pure nitrogen flowing, but the addition of 8–10 vol.-% oxygen to the nitrogen was required. This would result in a secondary combustion flame downstream from the decomposition flame. The double flame stabilized the system and allowed measurements at lower pressures. Hydrazine of a higher quality with only 0.5% aniline would burn without oxygen addition. Up to 2.5 mass-% water in the fuel seemed to have no effect. The mass burning rate determined by the droplet method,  $2.2 \times 10^{-2} \text{ g cm}^{-2} \text{ s}^{-1}$ , agreed well with data determined by the strand burning method, for example,  $2.4 \times 10^{-2} \text{ g cm}^{-2} \text{ s}^{-1}$  [1411]. The droplet mass burning rate is proportional to pressure, in contrast to low-pressure burning of hydrazine in tubes, where the rate is independent of pressure [1411]. The flame speed of a pre-vaporized hydrazine flame (120 cm/s) is much higher than that calculated for vapor emerging from a hydrazine droplet (~21 cm/s for the 0.5% aniline and 15 cm/s for the 1.5% aniline-containing hydrazine). The authors believed that the presence of aniline inhibited radical chains and thus lowered the flame speed.

#### 4.11.1 Decomposition of Hydrazine Droplets in an Atmosphere of Hot Combustion Products

A study of the decomposition of hydrazine, MMH, or UDMH droplets in an atmosphere of hot combustion products used single droplets suspended from a 100- $\mu\text{m}$ -diameter quartz filament as well as porous Alundum spheres [1433–1435]. Droplet diameter could thus be varied from 0.11 to 1.91 cm. The fuel droplets were burned in the hot gaseous combustion products of a flat-flame burner to simulate bipropellant rocket engine operating conditions. The flat-flame burner could be fed with lean fuel mixtures, generating oxygen-rich hot gases in which secondary combustion of the droplet vapor decomposition products would take place. The conditions included 1660–2530 K at ambient pressure. The results of the tests with oxygen excess are discussed in Section 4.14. As far as the monopropellant burning is concerned, the following results were obtained for hydrazine: The hot gas velocity was low enough to avoid turbulent flow; the Reynolds numbers around the droplets were less than 38. In all suspended droplet tests, plots of diameter squared as a function of time were

reasonably linear. Decomposition flames were not luminous at all, but oxidation flames of all three fuels showed two distinct zones of luminosity.

A theoretical combustion and flame structure model was developed similar to and based on models suggested earlier [1436–1438]. In this method the monopropellant flame was assumed to be infinitely thin and located at a position where the unreacted gas flows into the flame at the laminar flame speed of the monopropellant vapor. The hybrid model (with another second flame front) reduced to pure monopropellant burning if no oxidizer was present. Assuming  $E_{\text{act}} = 0$ ,  $T = 2060$  K, and  $v_{\text{ambient}} = 55.7$  cm/s, good agreement of experimental and theoretical data was achieved. The hydrazine burning rate was relatively independent of ambient temperature between 1700 and 2400 K, in particular for large droplet diameters. Whereas the results of the hybrid model and a bipropellant evaporation model were quite different for hydrazine, the distinction was not as pronounced for MMH or UDMH. The droplet burning rates for hydrazine are presented in Figure 47.

The mass burning rates predicted by the Allison-Faeth equation showed good agreement not only with experimental data of the same authors (Figure 47) but also with data from other investigators, such as [1431, 1432, 1439]. The data by Tarifa [1428] did not fit, and it was suspected that furnace radiation must be blamed for these high results.

Comparing the hydrazine and MMH decomposition rates of Figures 47 and 32 in the chapter on methylhydrazine, it is obvious that MMH monopropellant droplet burning proceeds more slowly than that of hydrazine in spite of higher volatility of MMH and increased luminosity of MMH decomposition flames.

#### 4.11.2 Other Studies on Droplet Combustion of Monopropellants

Imposed pressure oscillations may affect the burning rate of monopropellant droplets significantly. The phenomena can be described by a first-order perturbation analysis [1440]. A theoretical investigation was conducted on the open-loop combustion response of monopropellant droplets and sprays to imposed pressure oscillations. The theoretical model was solved as a perturbation analysis through first-order, yielding linear response results. Unsteady gas-phase effects were considered in some cases, but the bulk of the calculations assumed a quasi-steady gas phase. Calculations were conducted using properties corresponding to hydrazine decomposition. Zero-order results agreed with earlier measurements of hydrazine droplet burning in combustion gases. The droplet response was greatest (exceeding unity in some cases) for large droplets with liquid-phase temperature gradients; at frequencies near the characteristic frequency of the liquid-phase thermal wave. The response of a spray was less than that of its largest droplet; however, a relatively small percentage of large droplets provides a substantial response (exceeding unity in some cases).

Calculated steady combustion results and response predictions for large hydrazine droplets agreed favorably with earlier measurements [1441]. Droplet and

**Figure 47:** Hydrazine droplet monopropellant burning rate. (Reproduced and modified from [1433].)

spray response factors in excess of unity were found. High response was associated with high pressures (1–10 MPa), large droplets, large mean liquid temperature gradients, and frequencies near the characteristic frequency of the liquid phase thermal wave. Spray response factors are lower than the response factor of the largest injected drop; however, a small percentage of large drops can still provide substantial response for the combustion process [1442].

Depending on the geometry of the combustion chamber and the amount of attenuation provided, monopropellant droplet decomposition may lead to combustion instability and resonant effects [1443]. The burning-rate response of a condensed-phase fuel layer adjacent to a reacting gaseous boundary layer where the external flow has a longitudinal oscillation was examined to simulate the unsteady droplet burning in a liquid-propellant rocket and to try to isolate a physical mechanism that leads to in-

stability. The non-steady process is the heat transfer in the condensed phase. The results showed that the velocity-sensitive responses exhibited resonant phenomena at the proper frequency range and indicated that, under (un)favorable conditions, a liquid-propellant rocket can be driven to instability because of the thermal lag in the droplets.

There exists a large body of literature on the droplet combustion of monopropellants under various conditions in a combustion chamber. Some of these models are even applicable to the combustion of fuel sprays in a Diesel engine. Many of these publications apply to more than one monopropellant, but they are summarized here under hydrazine because this compound is the most important monopropellant, although it is rarely burned as a spray of droplets. For additional information on the theory and study of monopropellant droplet burning compare the following references: [1435, 1444–1473].

Most of these papers are quite general and only a few of them give data specifically applicable to hydrazine. Many of the experimenters had previously worked at one point or another with organic nitro compounds and nitrate esters as monopropellants and later used the same equipment and the same computer models to study hydrazine monopropellant droplet burning. Some of the droplet burning work was done to support the use of propylene glycol dinitrate/dibutyl sebacate mixtures as torpedo propellants.

A conventional formulation of quasi-steady radially symmetric burning of a pure spherical monopropellant droplet was re-examined assuming that the droplet undergoes adiabatic vaporization and exothermic direct one-step irreversible first-order decomposition burning [1474]. The singular near-equilibrium limit was examined by asymptotic analysis, and the dependence of the vaporization rate on the first Damköhler number was sought as that number becomes indefinitely large. In the near-equilibrium limit the flame was confined to a narrow spherical shell contiguous to the droplet. As the first Damköhler number became large without bound, some experimental and theoretical work has reported that the vaporization rate is proportional to the droplet radius squared, while other work has suggested that the vaporization rate is linearly proportional to the droplet radius. An analysis predicted that the maximum vaporization rate does not occur at chemical equilibrium (in contrast to bipropellant droplets). Further, in contradiction to previous work, it was indicated that for vaporization rate to be proportional to the droplet radius squared, the ratio of specific heat of vaporization to specific heat of combustion must be less than unity. It is this ratio which is important, not the non-dimensionalized droplet or ambient-state enthalpies.

#### 4.12 Heterogeneous Catalyzed Hydrazine Decomposition

Of all the possible modes of hydrazine decomposition, the catalytic mode is of prime practical importance. Countless (several thousand) satellites and space probes in op-

eration now use hydrazine for attitude control and orbit adjustment propulsion. All these spacecraft rely on the heterogeneous catalytic decomposition of hydrazine. Additional applications are for hydraulic and electric power in advanced fighter aircraft and, historically, at one time in both the US and Russian space shuttles. In many cases, the design of flightworthy hydrazine decomposition reactors relies on empirical design criteria, and very little helpful information can be derived from the few academic kinetic studies that have appeared to date. So far, nobody has been able to establish a reliable correlation between all the testing done with hydrazine decomposition in the laboratory at low pressures and the performance of hydrazine decomposition catalysts in rockets and gas generators at high pressures.

The low-pressure tests, mostly academic in nature, are useful in establishing the kinetics of heterogeneous hydrazine decomposition and establish a relative ranking of the catalytic activity of metals, working one's way all the way across the periodic table of elements (metals). Metals that have been identified as catalytically active must be avoided in materials of construction for hydrazine storage containers. The acceptability of steels containing less than 0.5% molybdenum remains a topic of discussion.

Hydrazine (hydrate) has been evaluated as a fuel for air-fuel cells. While catalytic decomposition of hydrazine as a monopropellant is highly desirable, it is very undesirable where hydrazine (hydrate) is in contact with electrodes in fuel cells, resulting in fuel loss even during idle periods of fuel cells.

A table in [1475] gives a chronological overview of the numerous publications devoted to the study of heterogeneous hydrazine decomposition. This table complements another table in [1188], which is restricted to homogeneous decomposition studies. A small number of these publications have practical applications. A complete review of all those publications would fill a book in its own right. A good summary of catalysts for rocket propulsion and gas generators, a first step in this direction, was written as a chapter of a handbook on heterogeneous catalysis [1476].

Heterogeneous decomposition of hydrazine has been studied in solution as well as in the vapor phase. The majority of these more academic investigations used a catalytic surface in ultra-high vacuum in combination with a mass spectrometer for product analysis. These studies relate only remotely to the decomposition of anhydrous hydrazine in a real-world reactor, whereas decomposition in solution may help to explain material compatibility or incompatibility of hydrazine with certain tankage materials. The metals under study and brought into contact with hydrazine were finely divided as a powder, as a skeleton catalyst, as a supported catalyst, as a wire filament, or as a freshly deposited thin film. A few metals were also tested as single crystals.

The main objective of many of the investigations discussed herein was to determine ground rules for the selection of more active decomposition catalysts, to study the decomposition mechanism, and to determine the activation energy of the decomposition of hydrazine in the presence of catalytic surfaces. Catalytic activity is closely related to the activation energy. Table 60 gives a summary of the activation energies

**Table 60:** Activation energy of heterogeneously catalyzed decomposition of hydrazine. (Metals in alphabetical order.)

| Metal     | Activation energy |              | Temp. range | Hydrazine partial pressure                          | References   |

on various metals and the conditions under which the measurements were obtained. This table focuses on metals for which activation energies have been reported and it gives numerical data for the activation energies and the conditions under which they were determined. The metal that achieves the most significant reduction of the activation energy of hydrazine (compared to data obtained in the absence of any catalyst) should make a good catalyst for future use in rocket engines.

These data may help in the development and selection of catalysts for hydrazine decomposition. In surveying the various metals that catalyze hydrazine decomposi-

tion, it was noted that transition metals having incomplete *d* subshells act as strong catalysts for hydrazine decomposition, whereas metals having no *d* subshells or completely filled *d* shells are not catalytic [1232, 1233]. It was theorized that electrons from the lone electron pairs in hydrazine interact with unfilled *d* orbitals in the early stages of adsorption and chemisorption of hydrazine. Other molecules with lone electron pairs, such as ammonia or aniline, block active sites and inhibit the catalytic decomposition of hydrazine.

#### 4.12.1 Heterogeneous Vapor-Phase Decomposition

The results to be discussed in this section can be subdivided and arranged in several ways: in chronological order, by experimental method, or by metal investigated. It has been decided to arrange the various references that are reviewed by experimental method and try to maintain a chronological sequence within each method. This can be done only at the expense of the clarity of the typical behavior of each of the metals investigated. The experimental methods used for studying heterogeneous vapor-phase decomposition include decomposition on thin films, single-crystal faces, polycrystalline wires, metal powders, or supported catalysts. The methods of monitoring the decomposition process include pressure rise, mass spectrometer analysis, field ion appearance spectroscopy, and electrical measurements. Electrical measurements include measuring the changing electric conductivity of thin films or the electron emission work function on metal wire tips while adsorption-desorption and decomposition is in progress.

#### 4.12.2 Vapor Decomposition on Thin Films

A high-vacuum apparatus was used to measure the rate of ammonia formation on a freshly deposited thin tungsten film at various temperatures in the range 195–273 K for study of the heterogeneous decomposition of hydrazine [1494]. The interpretation of the results was still based on the incorrect assumption that the dissociative adsorption of hydrazine would give amino radicals. This assumption was later shown to be wrong in view of results with <sup>15</sup>N-labeled hydrazine.

Subsequent investigations on the heterogeneous decomposition of hydrazine on tungsten and molybdenum films, respectively, were hampered by the lack of a mass spectrometer for product analysis [1495, 1496]. Instead, the authors had to rely on pressure rise measurements, fractionation of condensables, and selective adsorption on nickel films to draw conclusions on hydrazine decomposition mechanisms.

Hydrogen is selectively chemisorbed on freshly deposited nickel films, whereas nitrogen is not. The non-condensable gases passing through the liquid nitrogen trap could be analyzed in this fashion. The decomposition of hydrazine on tungsten films was explained as dissociative (as opposed to associative) chemisorption [1495]. A thin film usually contains all single-crystal planes in random mixture. It is not directly possible to state which face of the many crystals is more active than another face such as

is possible when a large single crystal is available to work with and the other faces can be isolated. From previous knowledge of the activity of tungsten single crystals in the adsorption of gases such as nitrogen, hydrogen, ammonia, and carbon monoxide, however, it was possible to derive which exposed crystal planes are most active in hydrazine decomposition. This was achieved by pre-adsorbing the four gases mentioned previously prior to the admission of hydrazine, in this fashion selectively blocking certain active sites. For instance, because the (110) plane of tungsten does not dissociatively chemisorb nitrogen from the gas phase, and carbon monoxide is adsorbed on this plane only subsequent to filling the more active (100) and (111) planes, the authors postulated that dissociative chemisorption of hydrazine occurred on the (100) and (111) planes, whereas molecular chemisorption took place on the (110) plane. Experimental evidence seemed to support this so-called two-plane theory.

Knowledge of the surface of the deposited metal film allows one to calculate the coverage of active sites by hydrazine. It follows that each  $\text{N}_2\text{H}_4$  molecule upon dissociative chemisorption on the (100) or (111) plane occupies four (H-adatom) sites. On the (110) sites the molecular adsorption may occur through a single hydrogen atom in the  $\text{N}_2\text{H}_4$  molecule. Thus, nitrogen and hydrogen are formed from decomposition on the (100) and (111) planes, whereas ammonia is formed without adsorption, most likely on the (110) plane.

In a similar study on hydrazine decomposition on molybdenum films, the results were qualitatively and quantitatively like those obtained on tungsten films [1496]. Both studies on tungsten and molybdenum were conducted at significantly lower temperatures than previous investigations. This may be one reason why results at higher temperatures included vapor-phase decomposition and indicated different mechanism. Other thin-film investigations measured the conductivity of nickel films prior to and during adsorption of hydrazine vapor [1497]. The change in resistance of Cu and Ni films during the decomposition of  $\text{H}_2\text{NNH}_2$  was studied between 297 and 423 K (24 and 250 °C) at partial pressures of  $\text{H}_2\text{NNH}_2$  ranging from 1.3 to 1.9 kPa (10 to 14 mm Hg). In the presence of  $\text{H}_2\text{NNH}_2$ , the resistance of the Ni film was found to increase rapidly owing to chemisorption of  $\text{H}_2\text{NNH}_2$ . Upon complete decomposition of  $\text{H}_2\text{NNH}_2$  the resistance was observed to decrease slightly, only to increase again, because a surface nitride  $\text{NiN}_3$  apparently was being formed.

Surprisingly, even hydrazine molecules adsorbed on aluminum, an otherwise totally inert metal, will dissociate at very low temperatures. Based on results with XPS, at 85 K both  $\text{NH}_3$  and  $\text{N}_2\text{H}_4$  are adsorbed molecularly, with N(1s) peaks at 400.5 eV [1498]. At 290 K hydrazine was initially adsorbed to give an N(1s) peak at 399 eV, but with time and additional exposure, the location of the peak shifted to lower photoelectron potentials, finally approaching 397 eV after heating the adatom layer to 390 K. One may assume that hydrazine underwent a slow dissociation

possibly with further decomposition to hydrogen adatoms that tenaciously adhere to the metal surface and prevent the adsorption of more hydrazine. As expected, ammonia dissociates more slowly than hydrazine. Hydrazine vapor will decompose on thin films of iron, nickel, or copper [1499]. Thin metal films were deposited inside a 240-mL glass flask by metal vapor deposition in high vacuum. The surface areas of the films were characterized by krypton adsorption prior to each test when varying amounts of hydrazine were admitted to the evacuated flask and the pressure recorded and the gas composition measured with a mass spectrometer within 1–3 min. after admission of the hydrazine. The temperature of the flask was varied from 273 to 393 K. The surface coverage  $\theta$  of hydrazine on the film was expressed in terms of multiples of the volume of the krypton monolayer and ranged from 0.6 for Fe to 0.73 for Ni and 1.5 for Cu at 243 K. Fast, dissociative chemisorption of hydrazine occurred on iron films at 243 K and the decomposition led to the evolution of  $N_2$  and  $NH_3$  within less than 1 min. Hydrogen became the main gaseous product above 393 K. Hydrazine adsorption and decomposition on nickel was like that on iron. Hydrazine as adsorbed on copper, but no decomposition occurred below 303 K. It was suggested that two-point attachment of the lone electron pairs in  $>N-N<$  to the copper crystal lattice could occur without a significant strain on the molecule.

A few tanks and expulsion diaphragms for some hydrazine-fueled satellites and missiles are made from stainless steel. Sometimes stainless steel is covered with thin films of rust in places where it has been welded and lost its passivity toward moisture in air, which is a problem. These rust films may cause accelerated decomposition of hydrazine (liquid or vapor) if the tank is not properly cleaned after the welding step. Quite often, residual pickling acids are left sitting in the hardware too long before they are cleaned out. In this case corrosion continues and salts are deposited in places where the acid/water solution dries out. In all these cases, it would be desirable to have a realistic non-destructive acceptance test to verify the compatibility of the tank with hydrazine before it is filled with liquid hydrazine. An all-up pre-flight test with liquid hydrazine would consume too much hydrazine and add to the headaches of removing all the hydrazine after the test, cleaning the tank, and keeping it clean prior to flight. Instead of using liquid hydrazine, a method has been devised that uses hydrazine vapor at very low partial pressures. In a carefully thermostatted chamber and with sensitive pressure transducers, contaminated tanks can be recognized by accelerated pressure rise [1500, 1501].

#### 4.12.3 Vapor Decomposition on Hot Wires and Metal Foil

An activation energy of 39.3 kJ/mol (9.4 kcal/mol), a pre-exponential factor of  $1.79 \times 10^7 \text{ mol}^{-0.24} \text{ s}^{-1}$ , and a reaction order of 1.24 were measured in the catalytic decomposition of hydrazine vapor on tungsten filaments at an initial  $N_2H_4$  pressure of 202 Pa (1.52 mm Hg) and a temperature of 440–487 K [1491–1493].

When hydrazine vapor was decomposed on an electrically heated platinum filament in a flow reactor at 13 mPa ( $10^{-4}$  mm Hg), several observations suggested the formation of diazene as an intermediate [1502]. Three molecules of hydrazine were decomposed for every molecule striking the filament. The hydrogen:nitrogen ratio in the non-condensable fraction of the reaction products was 2.5:1, suggesting that a compound with a H:N ratio of less than 2:1 had condensed in the cold trap. By attaching the platinum filament flow reactor to the inlet of a mass spectrometer, short-lived intermediates in the decomposition products could be identified, including mass 30 ( $\text{N}_2\text{H}_2^+$ ) and mass 29 ( $\text{N}_2\text{H}^+$ ).

When oxygen was mixed with hydrazine, heating of the catalyst produced an increase of  $m/e$  30 by a factor of 4. This was attributed to the formation of NO because there was no concurrent increase in  $m/e$  29. If both  $m/e$  30 and 29 had increased, diazene might have formed by partial oxidation of hydrazine on the surface of the catalyst.

Using a  $0.0046 \times 0.07 \times 6.9$ -cm ribbon of polycrystalline iridium foil in an ultra-high vacuum system with an attached QMS, an attempt was made to identify adsorbed species that might interfere with the hydrazine decomposition activity of an iridium surface [1503]. The characteristics of the clean surface were studied first, followed by adsorption and desorption of nitrogen, hydrogen, and ammonia. Desorption spectra from the hydrazine-dosed iridium ribbon suggested that the dosed surface harbored nitrogen in three distinct binding states and hydrogen in two states. It also contained molecularly adsorbed ammonia. A common feature of the desorption spectra obtained from hydrazine-dosed and from ammonia-dosed iridium ribbons was the appearance of hydrogen and nitrogen peaks at and above temperatures close to 600 K. Less ammonia was recovered from the ammonia-dosed ribbon than from the hydrazine-dosed ribbon. The simultaneous appearance of hydrogen and nitrogen peaks at about 600 K suggested that they arose from a single-surface reaction step that involved a common intermediate, most likely adsorbed molecular ammonia. IR absorption observed by other authors had previously been attributed to adsorbed ammonia [1504, 1505]. Two modes of hydrazine decomposition have been postulated. In one mode, hydrazine dissociatively adsorbs on iridium degrading rapidly to  $\text{NH}^*$  (\* = adsorbed) nitrogen adatoms and hydrogen adatoms:

In the other mode, hydrazine molecules chemisorb by way of hydrogen abstraction and by way of subsequent interaction with another hydrazine molecule from the vapor phase to form ammonia and nitrogen:

These four reactions account for product stoichiometry observed at temperatures up to about 500 K. Between 500 and 600 K an ammonia-forming reaction such as

may take place, while above 600 K, ammonia formation virtually ceases, and nitrogen and hydrogen are formed by

and adsorbed ammonia rapidly decomposes to nitrogen and hydrogen. Adsorbed nitrogen in the  $\beta$  state has been shown to be responsible for the gradual loss of hydrazine decomposition activity of an iridium foil. The activity could be restored by heating to a temperature at which the  $\beta$   $\text{N}^*$  becomes desorbed. The persistence of  $\beta$  nitrogen on the iridium surface after exposure to hydrazine was verified by the examination of the catalyst with Auger electron spectroscopy (AES). The results obtained from the desorption from the iridium ribbon were useful for the interpretation of later results obtained by the same laboratory using Shell 405 catalyst (Section 4.13.2.2). The rate-determining step is the desorption of nitrogen from the catalyst surface. The activation energy for this step was determined to be 213 kJ/mol (51 kcal/mol), and the pre-exponential factor is  $1.1 \times 10^{-2} \text{ cm}^2/\text{s}$  [1503]. Dehydrogenated surface species such as  $\text{NH}$  and  $\text{NH}_2$  or  $\text{N}$  and  $\text{H}$  adatoms were also observed by XPS of hydrazine vapor decomposition on iron films [1506]. Iron is the main catalyst for industrial ammonia production. If hydrazine is formed as an intermediate in ammonia synthesis, it may adhere to iron surfaces differently than ammonia would.

The decomposition of hydrazine on iridium wire and a catalyst surface closely simulating that of Shell 405 was studied using a molecular beam method and a TOF mass spectrometer [1482, 1483]. One objective of the study was to determine the extent of active site occupation by hydrazine and its decomposition products at lower temperatures (<600 K). The desorption of these molecules above a certain temperature will cause a sudden increase in reaction rate with increasing temperature. The experiments were conducted in a flow reactor where helium with a small amount of

hydrazine (1–3%) was flowed past the helix-shaped catalyst at 130 Pa (1 mm Hg) pressure. After reaction, the gas mixture was passed through two skimmers and introduced directly into the mass spectrometer. The temperature of the bare wire or coated catalyst helix could be raised by passing an electric current through it. At the same time, its resistance was measured as a temperature indication. The global reaction rate of hydrazine decomposition on iridium wire was found to obey the following equation:

$$R_2 = 1.74 \times 10^{-4} \times e^{-\frac{5540}{RT}} \times C_{\text{N}_2\text{H}_4}^{1.39} \times C_{\text{H}_2}^{0.025} \times C_{\text{N}_2}^{0.00} \times C_{\text{NH}_3}^{0.05} \quad \text{mol s}^{-1} \text{cm}^{-2}$$

The activation energy was thus found to be 23 kJ/mol (5.54 kcal/mol) over a temperature range of 460–700 K. Below 430 K the rate was significantly lower, which was attributed to adsorbed hydrazine. The decomposition rate was weakly dependent on temperature, except in the range 450–500 K, where it was dependent on temperature. It was suspected that below this temperature a significant portion of the active surface area is covered with a strongly bonded species, which begin to desorb at 450 K. Similar phenomena had been observed on tungsten [1495] and molybdenum [1496]. For the alumina-supported iridium catalyst a similar rate equation was obtained, except that the activation energy is essentially zero. The order of the reaction is the same:

$$R_e = 2.7 \times 10^{-2} e^{-\frac{(1.6 \pm 1.09) \times 10^3}{RT}} C_{\text{N}_2\text{H}_4}^{1.33}$$

This equation was obtained in a lower temperature regime than that for bare iridium wire because the reaction became diffusion controlled above 500 K since the supported catalyst is more active than the bare wire. The degree of ammonia dissociation  $X$  (for a definition, see *Encyclopedia of Monopropellants*, in the chapter “Hydrazine Monopropellants”) was identical for both catalysts (0.25–0.35).

A molecular beam/hot-wire technique with a mass spectrometer was used to study the decomposition of hydrazine on polycrystalline palladium surfaces [1486], which was like the apparatus used in [1483]. The pressure was maintained below  $10^{-5}$  mm Hg. The palladium wire had a geometric surface of approximately  $3 \text{ cm}^2$  and could be heated by passing an electric current through it. The kinetics of hydrazine decomposition were investigated by deuterium exchange, thermal desorption spectra, and measurement of stationary decomposition conditions. Analysis of the percentage of  $\text{N}_2\text{H}_3\text{D}$  and  $\text{N}_2\text{H}_2\text{D}_2$  in the products of a  $\text{N}_2\text{H}_4 + \text{D}_2$  mixture passing over a palladium wire showed that some isotope exchange occurred even at room temperature. At 520 K, up to 25%  $\text{N}_2\text{H}_3\text{D}$  and close to 5%  $\text{N}_2\text{H}_2\text{D}_2$  were observed in the products, whereas the  $\text{N}_2\text{H}_4$  fraction decreased with temperature as a result of isotope exchange. The initial hydrazine  $\text{N}_2\text{H}_4$  partial pressure was extremely low,  $10^{-8}$  mm Hg. The rate of deuterium exchange as a function of deuterium:hydrazine ratio showed a maximum. At higher deuterium pressures the isotope exchange was inhibited by pre-adsorption of deuterium on the catalyst. This indicated that the exchange occurred with hydrazine in the adsorbed state. Thermal desorption spectra of decomposition products obtained after loading the metal wire with hydrazine at room temperature and heating rapidly (20 K/s) showed that nitrogen and hydrogen

formation are governed by the same rate-determining mechanism. Stationary decomposition was achieved with flowing hydrazine at approximately  $10^{-5}$  mm Hg. Hydrazine decomposition began already slightly above room temperature and was complete above 450 K. Nitrogen, hydrogen, and ammonia formation increased in this range until above 600 K, where the ammonia formation dropped off as a result of incipient ammonia decomposition. In interpreting the experimental results, the authors proposed the following mechanism consisting of a sequence of six reactions, in which the second reaction is the rate-determining step:

The formation of ammonia is attributed to stepwise progressive hydrogenation of hydrazine by way of the third and fourth reaction. The proposed mechanism acknowledges the results by Block [1048] and [1490], according to whom the dinitrogen is formed from nitrogen atoms in the same hydrazine molecule such as shown in the fifth reaction. The reaction on palladium was first order, in agreement with the foregoing mechanism, in particular the second reaction. However, in previous tests with a gallium arsenide catalyst, the authors postulated a one-half-order mechanism that would support Szwarc's repeatedly disputed mechanism

The decomposition mechanism is apparently strongly influenced by the substrate on which the decomposition occurs.

In studying the decomposition of hydrazine vapor on palladium foil at 413–493 K and 1.4–13.1 kPa in a circulating flow system, the investigators concluded that the kinetic data excluded a chain mechanism [1487, 1488]. At 413 K, nitrogen and hydrogen were the major products of decomposition. The activation energy was determined to 87.9 kJ/mol ( $21 \pm 2.5$  kcal/mol). At 493 K, ammonia formed along with nitrogen. A mechanism was proposed where sorption and surface intermediate complex formation constituted the rate-determining steps. Studies were also conducted on a semi-permeable palladium tube membrane. Hydrogen was found to inhibit the decomposition. The rate of nitrogen production was proportional to the hydrazine concentration to the 0.85<sup>th</sup> power and inversely proportional to the hydrogen concentration to the 1.4<sup>th</sup> power:

$$W_{\text{N}_2} = k \frac{p_{\text{N}_2\text{H}_4}^{0.85}}{p_{\text{H}_2}^{1.4}}$$

where  $W(\text{N}_2)$  is the rate of  $\text{N}_2$  production and  $k$  is a constant. The retardation of the reaction on palladium by hydrogen elevated to a power greater than 1 could not be explained by simply filling the surface with hydrogen. It must be related to the reversibility of intermediate steps in the reaction. The rate of ammonia formation was proportional to

$$W_{\text{NH}_3} = p_{\text{N}_2\text{H}_4}^{0.6} p_{\text{H}_2}^{0.14}$$

At 513 K on palladium foil, the amount of ammonia formed comprised only several percent of all the hydrazine decomposed. Since ammonia by itself does not decompose on palladium at 500 K, hydrogen must be formed directly by the decomposition of hydrazine.

A cross-flow filament reactor was used to study the partitioning of chemical energy release between solid catalysts and gaseous reaction products of hydrazine vapor decomposition [1507, 1508]. The platinum, iridium, or tungsten filaments (0.127 mm diameter) were heated to temperatures above 1000 K and measurements taken in a range of 900 to 2200 K. This technique allowed for isothermal conditions on the reacting surface, although conversions were very slight. The temperature of the impinging hydrazine vapor could be varied by an upstream, heater filament also made from Pt but kept at a much lower temperature so it would not enter into competition with the hotter, main filament. Not all reactions can proceed to equilibrium within the short contact time of hydrazine with the catalyst filament. Non-equilibrium desorption of  $\text{H}_2$  molecules from the catalysts was responsible for part of the exoergic reaction energy transport and removal. The hydrazine source was a 1-L flask in the thermostatted bath and kept at a low, constant vapor pressure ( $\pm 0.1$  mm Hg). At the temperatures of this study, no other intermediate ( $\text{NH}$ ,  $\text{N}_2\text{H}_2$ ) appeared to be involved in the decomposition, but the experimenters did not use a mass spectrometer and product analysis was only by thermoconductivity and gasometry.

The Langmuir-Hinshelwood mechanism assumes a single binding state with coverage-independent parameters (a Langmuir isotherm). A reaction  $\text{A} \rightarrow \text{B}$  is assumed to proceed via adsorbed species

In a study of hydrazine decomposition, residence time of hydrazine vapors in a 400-mL CRES reactor filled with hot, polycrystalline Pt or Rh wires at 1.3 to 93 Pa (10 to 700  $\mu\text{m}$  Hg) and 400 to 1700 K was 1 to 10 s [1509]. A sample of the reaction products was bled through a control orifice into a QMS for analysis. Unfortunately, additional cracking of hydrazine or ammonia occurred on the hot filaments of the mass spectrometer, and this amount of byproducts determined in a baseline test had to be subtracted from all results with the catalyst in place. Below 800 K, the rates of ammo-

nia and nitrogen formation were comparable, while nitrogen was the main product above 800 K. Above 800 K, the rates became temperature independent, most likely as a result of reactant flux/diffusion limitations. The results (rates of  $\text{N}_2$  and  $\text{NH}_3$  formation as a function of temperature) could be represented accurately by a Langmuir-Hinshelwood rate expression. In a similar study of polycrystalline iridium wires in the same apparatus, the rates of  $\text{N}_2$  and  $\text{NH}_3$  formation were measured at 300–1700 K and 1.3–40 Pa (0.01–0.3 mm Hg) [1510]. At high temperatures (>900 K), both rates were first order with respect to hydrazine pressure and were pressure independent at <700 K. The shape of the rate =  $f(T)$  curves could be represented accurately by Langmuir-Hinshelwood unimolecular rate expressions. The rate of  $\text{N}_2$  formation rose rapidly with temperature but became flux-limited above ~800 K.

The identification of diazene in the intermediates of hydrazine or ammonia vapor-phase decomposition may hint at one of the inhibiting species suspected to linger on hydrazine decomposition catalysts at temperatures around 400 K. Most of the earlier studies on diazene as an intermediate in hydrazine decomposition were done in the liquid phase. Now diazene has been identified as an intermediate of the thermal, surface-catalyzed gas-phase decomposition of hydrazine or ammonia at 180–500 K on a polycrystalline rhodium foil [1237, 1238]. The experiments were performed in an ultra-high vacuum system equipped with AES, low-energy electron diffraction, and a multiplexed mass spectrometer. Low and high levels of hydrazine coverage on the metal foil were studied. At higher hydrazine coverage (near monolayer coverage), diazene was found along with adsorbed hydrogen, nitrogen, and ammonia. Diazene was identified at foil temperatures above 220 K based on mass spectrometry of the parent ion at 30 amu and a single-dehydrogenation fragmentation product at 29 amu that is present at 6% of the abundance of its parent. Adsorbed NH was already proposed earlier as an intermediate residing on the surface, but its dimer had so far not been seen. Co-adsorption of hydrogen increased and co-adsorption of oxygen decreased the diazene yield.

A modulated molecular beam mass spectrometer incorporating TOF and threshold ionization capabilities was used to study the decomposition of hydrazine vapor on a platinum foil at 773–1373 K and <186 Pa (<1.4 mm Hg) [1511].  $\bullet\text{N}_2\text{H}_3$  radicals and diazene were found at 773–973 K, but no  $\bullet\text{NH}_2$  radicals.

#### 4.12.4 Vapor Decomposition on Surface of Single Crystals

Most catalytic decomposition studies of hydrazine vapors at low pressures were done on polycrystalline foils, thin films, or wires. It has been found that the different surfaces of a well-formed single crystal can have widely varying activities for the decomposition of hydrazine. Thus, for supported catalysts, it would be desirable to select deposition methods that maximize crystal surfaces with high activities [577, 1506, 1512–1529]. The decomposition studies on single-crystal surfaces help to explain the cat-

alytic decomposition kinetics of hydrazine decomposition and may even aid in the development of improved supported catalysts.

From experiments using  $^{15}\text{N}$ -labeled hydrazine it was concluded that the product  $\text{N}_2$  is always formed from a single hydrazine molecule, based on data obtained on platinum single crystals [1048]. Imidogen free radicals adsorbed on the (111) surface of nickel single crystals during the decomposition of hydrazine can be identified by their IR spectra [1516]. The same has been observed for diimine on the (100) surface of Ni single crystals [1518]. A lack of mobility of the reaction intermediates  $\text{NH}_2$ ,  $\text{NH}$ , and  $\text{N}$  favors the recombination of two nitrogen atoms originating from the same hydrazine molecule on alumina-supported catalysts [1530, 1531]. Co-adsorption of  $\text{CO}$  or  $\text{D}_2$  with hydrazine on  $\text{Rh}(100)$  surfaces was studied with TPS, XPS, and ultraviolet photoelectron spectroscopy (UPS) in an effort to identify the active sites [1521, 1522]. The metal-CO bond was weakened by the presence of nitrogen. At 500–550 K,  $\text{N}$  was the only species remaining on the surface. On the other hand, pre-adsorption of molecular oxygen enhanced the decomposition and oxidation of hydrazine on  $\text{Pt}(111)$  crystal faces [559, 1525]. There is something peculiar about the activity of iridium as a catalyst for the decomposition of hydrazine. A new method, called angularly resolved temperature-programmed decomposition on single-crystal surfaces, has been applied in an effort to identify the geometric arrangement of the reacting species on active sites [1532, 1533]. It has been noted that nitrogen molecules desorbing from a clean surface of an iridium single crystal after depositing hydrazine vapor at 80 K followed by quick (100 K/s) warming will not radiate uniformly as expected by a cosine distribution. Instead, one of the three temperature programmed desorption (TPD) peaks, the one desorbing first at 290 K, showed a strong angular dependence, such that most of the nitrogen is ejected perpendicularly to the surface. This sharp angular dependence indicated that the desorbing molecule experienced a strong repulsive potential as it left the surface. It also allows some speculation about the orientation of the hydrazine molecules from which the nitrogen molecules originated.

With the use of a supersonic molecular beam-scattering system, the decomposition of hydrazine on  $\text{Ir}(111)$  surfaces has been studied in the temperature range 200–1500 K [1523, 1529]. While the sensor was placed at an angle of  $45^\circ$  to the surface, there was a temperature interval in which essentially no nitrogen was produced. This is in direct conflict with the decomposition stoichiometry. It was found that the nitrogen emission (= effusion) between 200 and 320 K had an extremely strong angular dependence. This was the first time a pronounced angular dependence of nitrogen emission had been observed for surface decomposition.

Experiments and computer simulations of hydrazine decomposition on  $\text{Ir}(111)$  surfaces of single crystals were combined in order to gain a better understanding of the  $\text{N}_2\text{H}_4$  decomposition on Ir catalysts [1524]. Metallic Ir rather than  $\text{IrO}_2$  was identified as the active phase for hydrazine decomposition.

#### 4.12.5 Vapor Decomposition on Metal Powders and Supported Catalysts

Results obtained on thin films and single-crystal surfaces help to interpret the results obtained on more complex surfaces, such as on metal powders and supported catalysts, but they only work at very low pressures. This is where the practical value of these investigations comes to bear if they result in the discovery of more active or less expensive catalysts for the decomposition of hydrazine in energy conversion systems. The most important reaction is the heterogeneous decomposition of hydrazine on supported iridium catalysts. In addition to supported iridium catalysts, numerous other supported metal catalysts have been investigated. These publications can be subdivided into those on noble metal catalysts and those on non-noble metal (generally ferrous metal) catalysts. According to their importance, the noble metal catalysts are discussed here first.

A TOF mass spectrometer was used to study the decomposition of hydrazine in a 15-cm (6-in.)-long reactor at 2.7–10.6 Pa (20–80  $\mu$ m Hg) filled with Shell 405 pellets [1534]. Complete decomposition was achieved if the catalyst was heated to 770 K, whereas without catalyst (thermal decomposition only) some hydrazine remained undecomposed even at 1170 K. Certainly, the pressure in this experiment was so low that the collision rate was very small, and some hydrazine passed undecomposed. At higher pressure, such as in a gas generator, complete hydrazine decomposition would occur. Besides hydrogen, nitrogen, and ammonia,  $\text{NH}_2$ ,  $\text{N}_2\text{H}$ ,  $\text{N}_2\text{H}_2$ , and  $\cdot\text{N}_2\text{H}_3$  radicals were also observed in the reactor effluent. Another surprising observation was the tenacity with which carbon dioxide was held by the catalyst despite 20 h of degassing in vacuum at 770 K before use. This may have implications for the repeated use of hydrazine propulsion systems after landing on Mars or in other carbon-dioxide-laden planetary atmospheres.

Temperature-programmed desorption of hydrazine decomposition products from catalyst surfaces helps to elucidate the hydrazine decomposition mechanism. Comparison of hydrogen TPD spectra of hydrogen adsorbed on iridium powder and on alumina-supported iridium indicated that the supported iridium had four instead of only two peaks [1504, 1505, 1535, 1536]. This indicated the formation of new bonding states formed by the interaction of the active metal with the carrier. Although nitrogen was not adsorbed from the vapor phase between 298 and 973 K, desorption spectra recorded after adsorbing and decomposing of hydrazine showed a new desorption peak, which was attributed to nitrogen remaining adsorbed on iridium. This corresponds to a desorption activation energy of 58 kJ/mol and confirmed that the first step of decomposition is the formation of a bond between nitrogen atoms of the hydrazine molecule and the unfilled *d* orbitals of the metal. The IR spectra of catalyst surfaces and adsorbed intermediates and products have also helped to elucidate the decomposition mechanism.

The use of Shell 405 catalyst provided more surface area than did a plain metal ribbon to study the chemisorption and desorption of adspecies that were previously found to reduce the catalytic activity of an iridium metal ribbon [1503]. The catalyst

was particularly useful for this study because of its high active metal loading and relatively large iridium surface area. The objective of the work reported in a series of publications was to elucidate the causes of catalytic activity loss that occurs in operational monopropellant thrusters and to determine the mechanism of heterogeneous hydrazine decomposition on commercial catalysts [1537]. At room temperature the steady-state decomposition of hydrazine over an alumina-supported Ir catalyst was found to yield  $\text{NH}_3$  and  $\text{N}_2$ , while at temperatures above 800 K the products were  $\text{N}_2$  and  $\text{H}_2$ . Following exposure of the catalyst surface to  $\text{N}_2\text{H}_4$ , the adsorbed species were studied by a temperature-programmed desorption technique at a heating rate of 2 K/s. The desorption products included  $\text{N}_2$ ,  $\text{NH}_3$ , and  $\text{H}_2$  originating from different binding states. For the more strongly bound nitrogen [ $\text{N}_2(\beta 2)$ ] the kinetics of desorption following exposure to  $\text{N}_2\text{H}_4$  were of first order with a desorption rate constant of  $3 \times 10^7 \exp(-26800/RT) \text{ s}^{-1}$ . Pre-adsorption of oxygen on the iridium catalyst was found to decrease the nitrogen binding energy and increase the nitrogen coverage. The surface coverage of all adsorbed species was found to be significantly smaller on catalysts that had already been used in pulse-mode monopropellant thrusters. The differences observed were correlated with the loss in the metal surface area of the catalyst. However, no differences in the binding energies of the various adspecies were detectable between fresh catalyst and used catalyst [1538–1540].

It was suggested that the temperature region around 450 K was the most detrimental to catalyst life under laboratory conditions, possibly due to adsorption of a surface contaminant or intermediate. This could have been the effect of aniline in the hydrazine used but was not recognized as such (see *Encyclopedia of Monopropellants*, in the chapter “Hydrazine Monopropellants”).

In the experimental setup, a 0.1-g catalyst sample was held in a vacuum system close to the inlet of a mass spectrometer. The catalyst could be exposed to hydrazine and/or adsorbing gases and would be heated at predetermined heating rates. Throughout the hydrazine exposure and TPD the composition of the offgassing could be analyzed in short intervals and recorded along with the catalyst temperature. The catalyst had to be reduced by repeated injections of hydrazine before reproducible results could be obtained. After the reduced catalyst had been exposed to hydrazine to saturation level, it was subjected to TPD, and the concentrations of each gaseous product leaving the surface was recorded as shown in Figure 48.

Ammonia desorbed in two very broad peaks located at 373 and 628 K, hydrogen desorbed in two nicely separated peaks at 383 and 673 K, whereas nitrogen resulted in a single peak with a maximum at 663 K. Water began to come off only at very high temperatures, most likely as a result of progressive dehydration of the catalyst carrier, alumina. When the tests were repeated at lower initial coverages, only the hydrogen peak at the higher temperature was occupied, but with increasing surface loading, the low-temperature hydrogen peak also became filled. The nitrogen was formed by a first-order process, and the activation energy and pre-exponential factor of nitrogen desorption from Shell 405 were determined to be 112 kJ/mol (26.8 kcal/mol) and

**Figure 48:** Temperature-programmed desorption peaks of ammonia, hydrogen, nitrogen, and water for hydrazine adsorption. (Reprinted and modified from [1537], with permission from ©1976 Elsevier; permission conveyed through RightsLink.)

$3 \times 10^7 \text{ s}^{-1}$ , respectively. Nitrogen desorption may be one of the rate-determining steps in hydrazine decomposition. The shape and location of the nitrogen peak was the same regardless of whether hydrazine or ammonia were adsorbed on the catalyst, but following ammonia adsorption, an additional small low-temperature nitrogen peak was observed, the origin of which is uncertain. The identity of the peaks and other observations support the conclusion that the hydrogen and nitrogen peaks formed during hydrazine decomposition at room temperature originate from an adsorbed ammonia intermediate. Studies by other authors with  $^{15}\text{N}$ -labeled hydrazine have indicated the absence of isotope mixing in the nitrogen formed from  $\text{N}_2\text{H}_4$  decomposition. The TPD results discussed here agree with the assumption that below 598 K the amount of ammonia decomposition is small, and the adsorption of hydrazine does not involve breakage of the N–N bond. There have been attempts to reduce the susceptibility of iridium on alumina catalysts (e.g., Shell 405) to inactivation by adsorbed products by depositing nickel on top of the iridium and alloying the two metals [1541]. Whereas rocket engine performance of alloy catalysts has so far always been inferior to Shell 405, laboratory studies using low partial pressures of hydrazine (2 vol.-%  $\text{N}_2\text{H}_4$  in He) showed that the mixed-metal catalyst system exhibited a pronounced activity maximum at a composition equivalent to 65 atom-% Ir/35% Ni. Whereas an all-iridium catalyst showed 52% activity loss after being exposed to  $3 \times 10^{-4} \text{ mol}$  at 448 K, the 65 Ir/35 Ni catalyst had lost only 27% of its activity under the same conditions. The results point to an electronic alloy effect. The affinity of a blocking intermediate to the surface is sufficiently decreased by the addition of Ni to prevent its accumulation on active sites. If pairs of iridium atoms in a specific steric arrangement were required

for the adsorption and decomposition of hydrazine, the progressive addition of nickel would dilute the iridium site density, but this is not what the experimental results indicate. It has been postulated that the decomposition of hydrazine may start with hydrazine dimers that are associated through hydrogen bonding, but there was very little proof for this theory [1542].

A very thorough investigation of the decomposition of hydrazine vapor on supported catalysts carrying metals of group Ib and group VIII of the periodic table of elements investigated iron, cobalt, nickel, copper, ruthenium, rhodium, palladium, silver, iridium, and platinum [1477, 1478]. The activity and selectivity of these metals in the decomposition of hydrazine vapor were measured in the temperature range 333–433 K. *Activity* expresses the disappearance of hydrazine due to reaction according to the combination of two or more possible equations:

*Selectivity* is defined as the ratio of the rate of  $\text{N}_2\text{H}_4 \rightarrow \text{N}_2 + 2\text{H}_2$  to the sum of the reactions  $\text{N}_2\text{H}_4 \rightarrow \text{N}_2 + 2\text{H}_2$  and  $3\text{N}_2\text{H}_4 \rightarrow 4\text{NH}_3 + \text{N}_2$ . The higher the selectivity, the more ammonia will be decomposed. Depending on the application, it is desirable to have catalysts with low selectivity (for space propulsion) or high selectivity (for undersea buoyancy). The catalyst samples were prepared by impregnating 0.2- to 0.4-mm alumina granules with aqueous metal salt solutions, drying, decomposing, slowly heating in a stream of hydrogen to 773 K, and reducing at this temperature for 10 h. The active metal loadings were chosen such that all catalysts would create about equal conversions of the hydrazine fed in argon at atmospheric pressure with hydrazine partial pressures of 1.3–1.5 kPa. For this reason, iridium and rhodium active metal loadings were very low (0.01–0.08%), whereas silver and copper were deposited to 5% by weight in the finished catalyst. In a baseline test with bare alumina carrier, it was determined first that thermal decomposition does not contribute significantly until a temperature of 453 K is exceeded. All catalyst work was thus conducted below this temperature.

It was noted that under isothermal steady-state conditions all catalysts except for copper, silver, and cobalt lost up to 50% of their initial activity over the course of 5 h. The activity of copper remained unchanged, whereas that of silver and especially cobalt increased with time. The deactivation was reversible and disappeared after heating in argon to 673 K for 8 h. It was most likely caused by adsorbed ammonia. Activation energies were determined by repeating tests at different temperatures. Although the activation energies were almost identical regardless of the metal, the pre-exponential factors vary by four orders of magnitude between platinum and copper. The activities and the range of selectivities of the various metals are summarized in Table 61, in which the data show that activity and selectivity do not necessarily go hand in hand.

**Table 61:** Activity and selectivity of supported metals arranged by decreasing activity at 373 K.

| Metal | Activity <sup>a</sup>                                             | Selectivity range |                   |
|-------|-------------------------------------------------------------------|-------------------|-------------------|
|       | mol N <sub>2</sub> H <sub>4</sub> h <sup>-1</sup> g <sup>-1</sup> | At lower <i>T</i> | At upper <i>T</i> |
| Ir    | 25                                                                | 0.03              | 0.1               |
| Rh    | 7.5                                                               | 0.6               | 0.17              |
| Pt    | 1.7                                                               | 0.7               | 0.1               |
| Ni    | 1.7                                                               | 0.1               | 0.04              |
| Co    | 1.2                                                               | 0.008             | 0.025             |
| Ru    | 1.0                                                               | 0.03              | 0.06              |
| Pd    | 0.0025                                                            | 0.9               | 0.6               |
| Ag    | 0.002                                                             | 0.006             | 0.02              |
| Cu    | 0.0007                                                            | 0.01              | 0.04              |

<sup>a</sup> Presumably normalized to grams of active metal, not grams of catalyst.

Data source: [1477]

It should also be mentioned that the selectivity of Ru, Co, Ir, Cu, and Ag increased with temperature, whereas that of Ni, Rh, Pd, and Pt decreased with temperature. The latter three metals possess rather high selectivities in the vicinity of  $\gamma = 1.0$  at 333 K. When arranging the metals in order of decreasing activity, the sequence is

Iridium is 30000 times more active than copper at 373 K. *A priori* one might believe that rhodium is an equally good catalyst, but its increased selectivity may reduce practical interest [1477]. Similar relative rankings were derived from liquid-phase tests [1543]. The elements could be grouped into two groups by activation energy:

or by selectivity

The low activation energy in the group Ir, Ru, Rh explains, of course, why these metals are good hydrazine decomposition catalysts. If any of the metals formed stable nitrides, the hydrazine decomposition mechanism might be blocked. Of all metals listed in Table 61, only copper is known to form a stable nitride, which may be one explanation for its low activity.

In a continuation of these studies, one group of authors has concentrated on one representative catalyst from each group of high and low selectivity or activity, respec-

tively [1544, 1545]. In studying the kinetics, the researchers noted that under the conditions of their experiment, the order of hydrazine decomposition was zero in hydrazine on both iridium and platinum catalysts and regardless of temperature (333–423 K). Temperature had a marked effect on selectivity. That of platinum decreased from 0.8 to less than 0.1, and that of iridium increased from 0.03 to 0.08 when the temperature was increased from 323 to 422 K. Admixing of hydrogen or ammonia to the hydrazine feed had little effect on selectivity, whereas an increase in selectivity should have been expected based on existing theories. Both gases had an inhibiting effect, but activity recovered to normal levels as soon as the admixing of reaction products was discontinued. The authors concede that the mechanism is not yet completely understood.

The decomposition of hydrazine vapor on metal powders was studied at low pressures (10 mm Hg) [1479]. Two groups of three elements each were chosen to include neighboring transition elements within the same period of the periodic table of elements. The objective of the study was to study any possible periodicity of the catalytic activity of elements that differ by only one unit in the charge of their nucleus (atomic number). The catalytic activity was found to increase in the order  $\text{Cr} < \text{Mn} < \text{Fe}$  and  $\text{W} < \text{Re} < \text{Os}$ . One theory tried to explain this by the stability of the respective metal nitrides, which decreases in the same sequence, thereby facilitating the desorption of nitrogen and/or ammonia from the catalyst surface [1479]. Pre-adsorption of hydrogen on the metal powder resulted in more active catalysts. For this reason, hydrogen that formed during the decomposition also acted autocatalytically. The fraction of ammonia dissociation (for definition, see *Encyclopedia of Monopropellants*, in the chapter “Hydrazine Monopropellants”) was 0.1 for all metals. The activation energy decreased from Cr to Fe and from W to Os.

The activity of iridium catalysts was found to decrease by the accumulation of strongly adsorbed nitrogen-containing adspecies on the active sites [1503, 1537, 1538]. When testing alloy catalysts with up to 48 atom-% nickel (balance iridium) supported on alumina in a differential microreactor, it was shown that the activity of the catalyst could be maintained for a longer time than with pure iridium catalyst and that the degree of catalyst deactivation, caused by prolonged hydrazine exposure, could be greatly reduced [1546]. XRD indicated that annealing the Ni/Ir catalyst (Ni coated on Ir on  $\text{Al}_2\text{O}_3$ ) for 15 h in hydrogen at 723 K resulted in the formation of Ir/Ni alloy crystallites. AES revealed that the surface was enriched with iridium atoms. Based on these results, it was concluded that the surface bonding of NH and N adspecies to Ir is weakened by the addition of Ni atoms. Their presence in subsurface atomic layers affected the nature of the chemisorption bond between adsorbates and the active sites on the Ir-Ni crystallites.

Other studies on nickel catalysts supported on magnesium oxide showed that the activation energy is dependent on the absence or presence of dopants [1485]. On pure MgO the activation energy was 58.6 kJ/mol (14 kcal/mol). Doping of the carrier with gallium lowered the activation energy to 50 kJ/mol (12 kcal/mol), whereas doping with

lithium increased it to 70 kJ/mol (16 kcal/mol). Rare-earth metal oxide catalysts have been used extensively in the decomposition of hydrogen peroxide as a rocket propellant, but little is known about their utility for decomposition of hydrazines. Mixtures of lanthanide oxides with manganese oxide were patented for cleaning up hydrazine vapors vented from a tank, some containing 4000–5000 mg hydrazine/L in air and passing through the reactor at a space velocity of 10000/h [1547, 1548].

The decomposition of hydrazine vapor on supported iron catalysts had found sudden attention in view of the fact that it or some of the reactions involved in it may be intermediate steps in the industrial Haber-Bosch synthesis of ammonia, a reaction that is operated worldwide on a megatonnage scale every day [1549, 1550]. If the ammonia synthesis process could be quenched at a certain stage to isolate the intermediate hydrazine, and even if the yield was only 0.01%, that would drastically change the supply situation for this energetic chemical.

The reverse process, the hydrazine decomposition mechanism can be investigated by pulsed reaction chromatography [1551]. In this study, only ammonia and nitrogen, but no hydrogen, could be detected in the decomposition products of hydrazine on an iron catalyst supported on magnesium oxide at 473 K. Conclusive proof of the fact that the N–N bond of hydrazine is not split during the decomposition and formation of nitrogen was obtained by analyzing the decomposition products of  $^{15}\text{N}$ -labeled hydrazine on an MgO-supported iron catalyst with a mass spectrometer [1552]. No randomization was observed in this test that used a good quality  $^{15}\text{N}_2\text{H}_4$  of exceptionally high isotope content (better than 94.9%) mixed with  $^{14}\text{N}_2\text{H}_4$  of natural isotope distribution. The only  $^{14}\text{N}^{15}\text{N}$  in the decomposition products was that which originated from the 5.1%  $\text{H}_2^{14}\text{N}^{15}\text{NH}_2$  contamination in the  $^{15}\text{N}_2\text{H}_4$ . Despite the weak bond strength of the N–N bond, this bond remains intact when nitrogen  $\text{N}\equiv\text{N}$  is formed. No surface-adsorbed amino, imine, or atomic nitrogen species take part in the formation of nitrogen in the hydrazine decomposition as postulated by some authors, at least not on the iron [1552] and rhodium [1490] catalysts that have been used in isotope studies so far. However, surface-bonded amidogen (amino) and imidogen (imino) groups contribute to hydrogen and ammonia formation.

Partially  $^{15}\text{N}$ -enriched ( $\gamma = 0.463$ ) hydrazine diluted with known amounts of natural isotope distribution hydrazine ( $\gamma_0 = 0.0038$ ) was used to study the decomposition mechanism of hydrazine vapor at 4 kPa (30 mm Hg) on eight different catalytic metals supported on a low-surface-area  $\alpha$ -alumina [1530, 1531]. The active metals were Co, Cu, Ir, Ni, Pd, Pt, Rh, and Ru with active metal loading between 0.5 and 5 mass-%. In agreement with results obtained by other investigators on heterogeneously catalyzed or homogeneous vapor-phase decomposition of hydrazine, no randomization (“isotope scrambling”) was observed.

The hydrogenolysis of hydrazine vapor or decomposing on the surface of various supported metal catalysts allows further insight into the decomposition mechanism

of hydrazine. A pulsed microcatalytic GC technique was employed using helium or hydrogen as carrier gas [1553]. Selectivities defined by

$$S = \frac{[\text{NH}_3]}{[2\text{N}_2] + [\text{NH}_3]} 100$$

are listed in Table 62 for various metals and two different carrier gases.

**Table 62:** Activity and selectivity of supported metals arranged by decreasing activity at 373 K.

| Metal     | Selectivity with carrier gas |          |
|-----------|------------------------------|----------|
|           | Helium                       | Hydrogen |
| Co        | —                            | 76.2     |
| Fe        | 67.3                         | 77.2     |
| Fe(Al)    | —                            | 78.4     |
| Fe(Al, K) | 69.1                         | 80.9     |
| Ir        | 71.2                         | 85.0     |
| Mo        | —                            | 72.2     |
| Ni        | 72.6                         | 78.8     |
| Pt        | 69.8                         | 87.9     |
| Rh        | —                            | 83.0     |
| Ru        | 68.9                         | 85.1     |
| W         | 68.0                         | 74.2     |

Data source: [1553]

At a catalyst temperature of 473 K, the hydrazine decomposition was complete, but no hydrogen was detected. The theoretical selectivity for hydrazine decomposition through

is 66.67. The data with helium carrier gas were close to this number but were consistently higher. The deviation has been attributed to the retention of  $\text{NH}_3$  and  $\text{NH}_2$  or  $\text{NH}$  on the catalyst. When hydrogen was used as a carrier gas, the selectivity for ammonia formation was higher than the theoretical maximum, indicating that some nitrogen that otherwise would have ended up as molecular nitrogen became reduced to ammonia.

When the selectivity of nine of the metals was plotted against the enthalpy of formation of the oxides of these metals, a hyperbolic curve-shaped relationship was confirmed. Variation of catalyst temperature within  $\pm 40^\circ$  did not have a significant effect on selectivity. The interpretation of the hydrogenation results may help to explain the ammonia formation on ammonia synthesis catalysts, even though the mechanism of N—N bond splitting in hydrazine assumed by Aika, Okhata, and Ozaki [1553] has been proved wrong in the meantime.

Another method is to correlate selectivity with the enthalpy of adsorption of hydrazine on the catalyst. On catalysts with a low enthalpy of adsorption, hydrazine decomposition produced mostly  $N_2$  and  $H_2$ . On catalysts with a high enthalpy of adsorption ( $>520 \text{ kJ mol}^{-1}$ ), the reaction products were  $N_2$  and  $NH_3$  [1554].

The chemisorption of hydrazine precedes heterogeneous decomposition. The chemisorption of hydrazine on metals involves interaction with the electron orbitals, whereas chemisorption on non-conductors must occur by different mechanisms [1555]. In the presence of CO, the adsorption of ammonia or hydrazine on vanadium, iron, or nickel catalysts may result in the formation of isocyanate [1556].

The first attempt to measure exo-electron emission or structural changes in Shell 405 in a stream of hydrazine vapor at 1 Pa ( $10^{-5}$  mm Hg) in a scanning electron microscope was not successful, but this could be a useful method of observing active sites in action [1557–1560]. Thermal electron emission beginning at 523 K obscured the exo-electron effects that might have been observed as a result of hydrazine adsorption and decomposition.

Technetium is an unusual element; it is radioactive and does not occur naturally except in trace quantities as a decay product of other elements. In the periodic table of elements it is located between manganese and rhenium, both of which are catalytically active metals. One would not want to use supported technetium as a catalyst unless there was a special need, e.g., keeping the catalyst bed warm under its own power of radioactive decay [1561].

A chemically inert, ultra-high-vacuum-compatible, pulsed gas inlet system was used for studying decomposition of a hydrazine molecular beam on a planar  $Ir/Al_2O_3/NiAl(110)$  catalyst button [1562]. The inert, pulsed inlet system made it possible to measure decomposition products evolving from a small (2 mm) Ir-containing spot, despite the high propensity for hydrazine to prematurely decompose on the surfaces of inlet systems and vacuum chambers.

#### 4.12.6 Vapor Decomposition on Semiconductors or Organic Catalysts

Much of the electronic age owes its success to silicon semiconductors in transistors and integrated circuits and microprocessors on chips. It is interesting to note that these semiconductor devices are not only electronic conductors, but also catalysts. Under certain conditions, catalysis and electrical conductivity go hand in hand. Semiconductors can either be elements like silicon or germanium or compounds like gallium arsenide or certain metal oxides. Study of the decomposition of hydrazine on semiconductors can help in gaining a better understanding of the decomposition of hydrazine on metals where electrons flow more freely. However, these materials may not be suitable for operation at higher temperatures where metal oxides become reduced to the parent metals. Unfortunately, the thermal stability of these semiconductors and organic catalysts is insufficient to be of any use for hydrazine monopropellant reactors. They can potentially be used as electrode materials in fuel cells or electro-

chemical hydrazine vapor sensors. In view of the indicated catalytic activity of zinc oxide in semiconductor experiments, it may be a poor choice to include zinc oxide as a filler in diaphragm polymers for hydrazine tanks. Superconducting ceramic oxides can also catalyze the decomposition of hydrazine and hydrazinium ions.

#### 4.12.7 Computational Modeling of Catalyst-Hydrazine Interactions

Developing catalysts for any application, not only for the decomposition of hydrazine, is mostly an empirical process or trial and error. Attempts have been made to derive some guidelines for the selection of active catalysts based on the experience of generations of catalyst chemists. Modern computational chemistry based on quantum-chemical methods has been applied to model interactions between adsorbed hydrazine and catalytic surfaces, such as platinum [1563], copper [1513, 1564–1566], nickel [1567, 1568], silicon [1569], or iridium [1570].

The ReaxFF program was used to model the decomposition of hydrazine on catalytic surfaces Pt(100) and Pt(111) under various conditions [1373]. The presence of a Pt catalyst reduced the onset of decomposition temperature of hydrazine by about 50%. On single crystals, the Pt(100) surface was 20 times more active for hydrazine decomposition than the Pt(111) surface, in qualitative agreement with experiments.

The bond-order conservation method was used to examine the catalytic decomposition of  $\text{N}_2\text{H}_4$  on metal catalysts for the study of catalytic selectivity [1571]. Variation in the activation energy,  $E_{\text{act}}$ , of the most relevant steps was calculated as a function of the enthalpy of adsorption of nitrogen,  $Q_{\text{N}}$ , between 0 and 1250 kJ/mol. In the present case there are three ranges of enthalpy of adsorption of nitrogen, corresponding to different catalysts, each of which favors one route. Results suggested that below  $Q_{\text{N}} = 520$  kJ/mol the catalytic decomposition of  $\text{N}_2\text{H}_4$  produces mostly  $\text{N}_2$  and  $\text{H}_2$ . Above  $Q_{\text{N}} = 520$  kJ/mol,  $\text{NH}_3$  and  $\text{N}_2$  are the main products. Near  $Q_{\text{N}} = 520$  kJ/mol, a mixture of  $\text{N}_2$ ,  $\text{H}_2$ , and  $\text{NH}_3$  is obtained, in agreement with experimental results on different metals.

### 4.13 Heterogeneous Liquid-Phase Decomposition

Liquid-phase decomposition is often preceded by adsorption of the liquid on an active surface of a high-surface-area material and release of the heat of adsorption. In some cases, the energy released initially is sufficient to vaporize all hydrazine and then the decomposition continues as a vapor-phase decomposition.

#### 4.13.1 Heterogeneous Thermal Decomposition of Hydrazine

Thermal decomposition of hydrazine can occur over a wide range of temperatures. By *thermal* we mean hydrazine by itself or in contact with an inert container wall as

long as one works in a gravity field. Thermal decomposition implies the absence of a catalyst. Catalytic decomposition of hydrazine in monopropellant reactors will be discussed in *Encyclopedia of Monopropellants*, in the chapter “Hydrazine Monopropellants,” of this book. Depending on the temperature environment, thermal decomposition can occur slowly or quickly. The slow, unwanted liquid-phase decomposition of hydrazine during storage was already discussed in Section 4.1. The current section deals with liquid hydrazine decomposition under conditions other than storage. In particular, here we are interested in very rapid liquid-phase reactions that precede the controlled catalytic decomposition of hydrazine when it comes into contact with a catalyst. These reactions are of considerable commercial interest. The mechanism of heterogeneous hydrazine decomposition in the liquid phase is very similar to that in the vapor phase, except it is sometimes very difficult to exclude solvent and surface interference. The mechanism of heterogeneous decomposition in anhydrous hydrazine is very difficult to study because measurements are restricted to less active catalysts. At low temperatures (room temperature), isothermal experiments often extend over months or years. The more active catalysts will immediately cause a temperature increase because of the strong exothermicity of the reaction, and it becomes impossible to maintain isothermal conditions needed to make kinetic measurements. On the other hand, the study of heterogeneous hydrazine decomposition is also closely related to liquid-phase stability studies described in Section 4.1, in particular material compatibility studies described in Section 5.3 and autodecomposition safety studies described in Section 8.2.3. At least four different equations can be used to describe the stoichiometry of the heterogeneous decomposition of hydrazine in solution:

Or, in more general terms, combining the four preceding conditions:

These reactions may take place simultaneously or preferentially, depending on the reaction conditions and the type of catalyst used. The thermal decomposition of hydrazine was studied in packed reactors filled with platinum-rhodium wire mesh or molybdenum beads [1572].

Another method to study strictly thermal decomposition of liquid hydrazine is in strand burners (Section 4.10.1) and in burners in which the flame is stabilized on a flame holder (Section 4.14.1) or in an inert porous medium (Section 4.9.2).

#### 4.13.2 Catalytic Decomposition of Liquid Hydrazine

When studying the catalytic decomposition of liquid hydrazine, be it unwanted decomposition in contact with container materials or desired controlled decomposition in a rocket engine, it is difficult to separate the effects of the wall materials of the test apparatus from the effects of the added material under study. For kinetic studies, it is difficult to maintain isothermal conditions because the heat of reaction immediately leads to a runaway temperature increase situation.

The production and characterization of catalysts for decomposition of hydrazine in rocket engines and gas generators will be discussed in more detail in *Encyclopedia of Monopropellants*, in the chapter “Hydrazine Monopropellants.” Here we are only looking at catalyst-hydrazine interactions from an academic point of view. There are many methods for producing more active and more durable catalysts for hydrazine decomposition. It is important to select the right type of carrier, the most active metal, and the optimum method for active metal deposition. All these more practical (less theoretical) aspects will be dealt with in *Encyclopedia of Monopropellants*.

##### 4.13.2.1 Catalytic Decomposition of Liquid Hydrazine on Metal Powders

The current section deals mostly with attempting to define the thermal stability of hydrazine in mathematical terms using kinetic theory, identifying intermediates and rate-determining reaction steps. This section deals with the decomposition of hydrazine at higher temperatures than are typically encountered during storage. The slow decomposition of liquid hydrazine during storage was already covered in Section 4.1. The two sections complement each other, and there may be some overlap. Both sections should be read side by side when trying to determine the likelihood of unwanted hydrazine decomposition under conditions of use. The current section helps in selecting materials that hydrazine may be exposed to in the hotter sections of a rocket engine, such as during heat soak back in the injector. It also deals with the problems mostly from an academic point of view, not necessarily related to specific hardware such as valves or rocket engine injectors. Data in the current section also help to identify metals with an undesirably high activity for catalyzing hydrazine decomposition in materials of construction but that may make good catalysts for hydrazine decomposition in monopropellant thrusters. One of these examples is molybdenum, which one must exclude from hydrazine storage tank materials, but it makes a modestly active catalyst (although less active than platinum-group metals).

Tests of highly concentrated (>90%) hydrazine with nickel, cobalt, iron, aluminum, copper, silver, or platinum had shown that only Raney nickel and Raney cobalt brought about rapid decomposition at room temperature [1484, 1573]. In particular, Raney nickel was a catalyst of reproducible quality, and its effect on the decomposition of hydrazine was studied in more detail. The decomposition of hydrazine was studied by measuring the rate of gas evolution. In these experiments, 0.003–0.5 g of Raney nickel was added to 3 mL hydrazine. The rate of gas evolution was directly proportional to the amount of catalyst added, typical for a heterogeneous

reaction. The rate remained constant over a 24-h period at 298 K. The results of measurements at six different temperatures between 274 and 323 K fitted nicely into an Arrhenius plot, and the slope of the line gave an activation energy of 71 kJ/mol = 17.1 kcal/mol. The decomposition products always contained some hydrogen. Tests with hydrazine-water mixtures revealed a maximum specific activity at eight molar hydrazine solutions. Hydrazinium salts, such as hydrazinium(2+) sulfate  $\text{N}_2\text{H}_6\text{SO}_4$ , caused an initial temporary acceleration, and rates of gas evolution sometimes dropped below those previously measured with pure hydrazine. Pre-treatment of Raney nickel with cyanide or sulfide (or admixture of sulfide or cyanide to the hydrazine) poisoned the catalyst, whereas platinum salts promoted its activity.

An advanced experimental method to study liquid hydrazine decomposition reactions is in an accelerating rate calorimeter (ARC). This method has now been complemented by the microcalorimeter, which can take heat flux data at lower temperatures than the ARC [1174]. While the ARC works at temperatures from 373 to 625 K, the microcalorimeter, owing to its increased sensitivity, operates at lower temperatures between 298 and 328 K. The ARC used at NASA WSTF for studying the acceleration of hydrazine decomposition reactions by various materials of construction was already described in Section 5.3.2 [1574]. It consisted of a 25-mm-diameter spherical sample holder vessel made of pure titanium weighing approx. 8 g by itself and 30 g with the adapter B-nut. Internal volume was 9 mL and surface area was 24 cm<sup>2</sup>. Gas evolved, causing the pressure buildup was analyzed for residual hydrazine and decomposition products after several runs. No residual hydrazine could be detected using a coulometric titration method. GC analysis showed the gas to consist of 81.7%  $\text{NH}_3$ , 18.2%  $\text{N}_2$ , and a trace (0.13%) of  $\text{H}_2$  (% numbers in vol.-%). Decomposition of 0.5 g hydrazine in the vessel caused a temperature increase of 115 K and a pressure increase to 12.5 MPa. The burst pressure of the titanium bulb was expected to be near 40 MPa. With hydrazine alone, the first detectable onset of exotherms was usually near 468 K [1575]. For the hydrazine-only baseline tests, the titanium bulbs were used only once to eliminate contamination and passivation effects. It was noted that the log temperature rate vs.  $1/T$  had a discontinuity and the log pressure vs.  $1/T$  curve had an inflection point near 515 K. It was shown that the discontinuity and the inflection point coincided with the point at which all liquid hydrazine was consumed and the remainder of the event took place in the vapor phase. While both liquid and vapor hydrazine are present and in equilibrium, the reaction has an apparent zero order and the activation energy in contact with titanium was  $98.3 \pm 1.7$  kJ/mol.

Metals in powder form were weighed into the sample holder and 0.5 mL hydrazine added in a glove box under nitrogen. With CRES-304L, the heat release rate for the sample holder vessel was proportional to the surface area of the stainless-steel powder added. The heat release rate (expressed as  $\text{J s}^{-1} \text{m}^{-2}$ , where  $\text{m}^{-2}$  is the reciprocal surface of the sample holder) was proportional to the surface area of the metal sample, when nickel powder, nickel turnings, and nickel foil were inserted into the titanium sphere. Surprisingly, chromium, aluminum, CRES-410L, and CRES-316L had very low

catalytic activity, which could not be discerned from the background effect caused by the titanium vessel alone. The catalytic effect of CRES-304L was distinct, but borderline. When normalized by the surface area, CRES-304L, iron, molybdenum, nickel, and cobalt had increasing catalytic activity in that order. Cobalt was the most active metal tested in this series at 353 K. In continuation of these studies, 0.5 mL hydrazine were mixed with 0.01–1.5 g of metal powders and tested in the ARC as above [1576]. The metals tested are summarized in Table 63 in order of decreasing activity.

**Table 63:** Relative activity of metal powders tested in accelerating rate calorimeter.

| Metal     | Activation energy, kJ/mol | Relative activity |
|-----------|---------------------------|-------------------|
| Co        | 43                        | 3900              |
| Ni        | 93                        | 310               |
| Mo        | 76                        | 94                |
| V         | 85                        | 66                |
| Fe        | 119                       | 33                |
| W         | 68                        | 11                |
| Au        | 74                        | 7.8               |
| Ti        | 95                        | 1.0               |
| CRES-304L | 100                       | 0.43              |
| Cr        | 105                       | 0.099             |
| Ta        | 106                       | 0.06              |

Data source: [1576]

The decrease in relative activity (calculated at 353 K from average activation parameters) parallels an increase in activation energy. The relative activity of iron stands out among the other metals, and its dissimilarity with nickel (one of the most active metals in the group) is remarkable. Nickel was also tested in four different particle sizes. The temperature rise rate was linearly proportional to the surface area of the particles.

The surface area of the nanoparticles of nanometals is extremely high and offers ways to make very active catalysts. This may work fine with hydrazine solutions at room temperature for releasing hydrogen for use in fuel cells, but at the typical much higher operating temperature of hydrazine monopropellant reactors, the nanoparticles would quickly sinter into a solid mass with very little activity.

#### 4.13.2.2 Catalytic Decomposition of Liquid Hydrazine on Supported Catalysts

The gas composition obtained during the heterogeneous decomposition of liquid hydrazine (diluted with water) on a 20% ruthenium on alumina catalyst (on 1/8 × 1/8-in. pellets) indicated an overall stoichiometry of [1577]

This can come about by simultaneous contributions from

and

Both reactions are first order with respect to hydrazine. The rate equations are expressed as

$$v_1 = 8.7 \times 10^3 e^{-\frac{54444}{8.314T}} \text{ c mol } N_2 \text{ g}^{-1} \text{ s}^{-1}$$

and

$$v_3 = 3.0 e^{-\frac{34000}{8.314T}} \text{ c mol } (N_2 + H_2) \text{ g}^{-1} \text{ s}^{-1}$$

The rate-controlling step was assumed to be the reaction between one  $N_2H_4$  molecule in the liquid phase and the adsorbed  $NH$  radical to form nitrogen and ammonia. Similar results were obtained on supported palladium and platinum catalysts (20% Pt or Pd on 1/8-in. alumina pellets) using the same experimental technique [1578]. The reaction products corresponded to the following overall reaction:

It was theorized that the initial, slow step is the dissociative chemisorption of hydrazine in the form of  $NH_2$  radicals. In accordance with the dual-plane theory of Cosser and Tompkins [1495], it was suggested that the adsorption process and subsequent reaction occur only on the active sites of these metals. Under certain conditions, such as with low hydrazine concentrations or during the beginning of a test, pre-adsorption of hydrogen on the palladium surface changed the stoichiometry of the evolved permanent gas. The observed kinetics were one-half order over the entire range of hydrazine concentrations (0.6 to 30.8M). On platinum catalysts, the order of reaction was also one-half at low concentrations but decreased to zero if hydrazine concentrations exceeded 25 mol/L. The hydrazine decomposition activity of the five noble metals tested by Sayer can be ranked in the sequence  $Ir \gg Ru > Rh > Pd > Pt$ .

One of the first of a long series of reports by Sayer et al. started looking at the reaction rates of hydrazine with 1, 2, or 4 Shell 405 catalyst pellets held in a rotating (300–350 rpm) basket with a retractable glass sheath [1579]. They used water dilution and three concentrations of hydrazine to slow down the reaction and extrapolate to 100%  $N_2H_4$ : 15.8, 29.8, 31.7, and 99%  $N_2H_4$  in  $H_2O$  and measured the rate of gas evolution as a function of initial temperature. From these data they derived an average activation energy of 65.4 kJ/mol (15.628 kcal/mol) and concluded that this is a heterogeneous first-order reaction, which is chemically controlled.

Subsequently, others studied the decomposition of hydrazine in aqueous solution (30.8 and 45 mass-%) on rhodium and iridium catalysts using  $^{15}N$ -labeled hydrazine [1480, 1490, 1580]. The most important result of this study was the finding that

the N—N bond of hydrazine remains intact when hydrazine decomposes on rhodium or iridium catalysts. The reaction mixture consisted of 30.8 mass-% hydrazine with a  $^{15}\text{N}_2\text{H}_4$  : normal  $\text{N}_2\text{H}_4$  molar ratio of 1 : 65.3. The  $^{15}\text{N}$ -isotope-labeled hydrazine contained 96.2 atom-%  $^{15}\text{N}$  and 3.8 atom-%  $^{14}\text{N}$ . A second dilution was made to obtain 45 mass-% hydrazine, in which the molar  $^{15}\text{N} : ^{14}\text{N}$  dilution ratio was 1 : 122.3. Gas chromatographic analysis showed that hydrogen and nitrogen were produced in equimolar quantities over the entire range of experimental conditions when the 20% rhodium on alumina catalyst was used. This would correspond to

However, with the Shell 405 catalyst (32% iridium on alumina), much less hydrogen was formed, as the molar ratio  $\text{H}_2 : \text{N}_2$  was only 1 : 200. Analysis of the nitrogen with a mass spectrometer showed that no randomization of the nitrogen isotopes had occurred and the amount of  $^{14}\text{N}^{15}\text{N}$  was equal to that initially present as  $\text{H}_2^{14}\text{N}^{15}\text{NH}_2$  in the mixture. However, as previously reported, Davis and Sayer had observed a 50% randomization during oxidation of hydrazine with cerium(IV) sulfate [1277]. As far as the reaction order is concerned, it was found to be dependent on hydrazine concentration in the experiments with rhodium catalysts. Over the concentration range 0–20 mass-% the rate of decomposition was approximately proportional to the square root of the hydrazine concentration. When the hydrazine concentration was increased, the reaction order changed from one-half to zero for concentrations in excess of 50 mass-%. This change indicated that the adsorption of hydrazine on the catalyst surface was a rate-determining step. Apparently, the decomposition products must desorb and diffuse away before more hydrazine can be adsorbed on the surface. The activation energy in the high-concentration range in which the reaction order is zero was determined as  $41.28 \pm 0.33 \text{ kJ/mol}$  ( $9.87 \pm 0.08 \text{ kcal/mol}$ ) with a pre-exponential factor of  $3.45 \times 10^2 \text{ mol g}^{-1} \text{ s}^{-1}$ .

The mechanism of heterogeneous hydrazine decomposition, in the words of Davis and Sayer

involves two hydrazine molecules, the two nitrogen atoms of one of these molecules form nitrogen gas without N—N bond fission, and the slow step in the reaction involves the dissociative chemisorption of the hydrazine molecule. The dissociative chemisorption of hydrazine gives adsorbed amide radicals, and these further dissociate to imine radicals and hydrogen atoms, the latter combine and are desorbed as hydrogen gas.

On the Shell 405 catalyst and in aqueous solution, activation energies of hydrazine decomposition were determined in three different conditions [1480]. A “well-stirred” reactor was used in this study by mounting the catalyst pellets on the end of a rotating shaft. The activation energies for iridium tabulated in Table 60 were determined in 31.7 and 99.0% hydrazine, respectively. The decomposition of aqueous hydrazinium chloride solution on the same catalyst had a slightly lower activation energy than that of pure hydrazine. The first-order reaction is assumed to be chemically controlled, not

diffusion controlled, because activation energies of diffusion-controlled reactions are usually significantly lower, on the order of 8–16 kJ/mol (2–4 kcal/mol). The isotope labeling indicated that the N–N bond was not split during decomposition, either in free hydrazine or in hydrazinium chloride.

The rate of reaction of liquid hydrazine in contact with supported catalysts is determined by kinetics and in many instances by the diffusion of reactants to and products from the catalyst surface. In the case of hydrazine and Shell 405, the ignition delay is of crucial importance for the response of rocket thrusters and also for the survival of the catalyst itself. An excessive induction period allows liquid hydrazine to wick deeply into pores of the catalyst structure, and the sudden pressure increase caused by delayed hydrazine decomposition causes the catalyst to split. The induction period has been studied by high-speed cinematography [1581] and by pressure-rise measurements [1582]. Pressure-rise measurements gave decomposition rates of  $16.5 \times 10^{-4} \text{ mol g}^{-1} \text{ s}^{-1}$  at 310 K and an activation energy of  $12.7 \pm 1.1 \text{ kJ/mol}$  [1582]. The tests were conducted by dropping a 1/8 by 1/8-in. pellet into liquid hydrazine and measuring the pressure rise. Pre-adsorption of ammonia increased the induction period. The results of most of the tests are questionable because some catalyst samples were not fresh. Furthermore, tests with granular catalyst would have been more meaningful because pellets are very rarely exposed to liquid hydrazine in the inlet portion of hydrazine reactors. The effects of additives and contaminants on decomposition of hydrazine on Shell 405 were measured [1583].

In another study, a catalytic surface was prepared by pressing a mixture of pulverized Centre National d'Etudes Spatiales – European Space Research Organization (CNESRO) (Ir-Al<sub>2</sub>O<sub>3</sub>) catalyst, graphite, and polytetrafluoroethylene (PTFE) together. Because these pellets had fewer active sites, kinetics could be studied without interference from excessive heat or gas evolution [1481]. Also, the pellets had good thermal and electrical conductivity, allowing rapid heat dissipation and study of catalytic phenomena on surfaces with superimposed electric potentials. From an Arrhenius plot an activation energy of 86 kJ/mol (20.5 kcal/mol) was derived. This is much higher than the 65 or 48 kJ/mol previously obtained by Sayer [1480] or Santacesaria, Guiffre, and Gelosa [1584], respectively. The effect of dissolving electrolytes in the hydrazine could not be studied with unequivocal results, because hydrazinium(1+) chloride or potassium chloride caused premature swelling and breakup of the catalyst pellet. Potassium hydroxide left the catalyst intact but had no effect on the catalytic rates. Therefore, a 0.05-M KOH solution in hydrazine was used for the experiments with polarized catalysts. Cathodic polarization slowed the catalytic decomposition to a complete state of inactivity, whereas anodic polarization restored the initial activity of the catalyst. It is theorized that adsorbed hydrazide ions play a role in this mechanism because they occupy the electrophilic sites of the catalyst, preventing access of the lone electron pairs of hydrazine molecules. The attachment of lone electron pairs of nitrogen in hydrazine to the active sites is thought to be the first step in catalytic hydrazine decomposition.

An interesting study on the kinetics of liquid hydrazine on iridium-alumina catalysts was conducted using both Shell 405 and the CNESRO catalyst [1585]. Most results were obtained for Shell 405. The experiments used a small bomblet holding 0.5–1.0 g catalyst. Hydrazine was injected with a syringe, and temperature and pressure were recorded on an oscilloscope using thermocouples and a pressure transducer. The ignition delay was defined as the time at which 5% of maximum pressure was reached. The  $p = f(t)$  curve was characterized by an inflection point. The authors theorized that below this point the temperature of liquid in contact with the catalyst rose adiabatically, until at the inflection point it exceeded the boiling temperature. From then on, the decomposition proceeded mainly as a vapor-catalyst interaction. The mechanism illustrated in Figure 49 was proposed, where the character **X** represents active sites on the catalyst surface and the dotted lines indicate electrons in motion.

**Figure 49:** Hydrazine decomposition reactions taking place at the surface of a catalyst.

The rate of hydrazine decomposition can be expressed as a function of all the kinetic rates of equilibrium reactions indicated by arrows in this scheme. Diazene is assumed to be an intermediate in the decomposition of hydrazine. However, the decomposition mechanism through N–N bond splitting proposed by the French authors is not supported by isotope studies (see preceding discussion).

The rate-determining step for hydrazine decomposition in the vapor phase is proposed to be the desorption of product ammonia. The desorption of ammonia and ni-

trogen from the surface is symbolically indicated by the upward-pointing arrow  $\uparrow$  in Figure 49.

The effect of initial CNESRO catalyst and hydrazine temperature on ignition delay could be accurately measured in this setup [1586]. At ambient pressure, ignition delay decreased linearly from 280 to 410 K. When the catalyst was above 360 K to start with, variation of the hydrazine temperature had little effect. When the catalyst was kept at 323 K to start with, warming of the incoming hydrazine from 283 to 313 K helped to shorten the ignition delay slightly (from 20 to 13 ms). Of particular interest for gas generator applications in a plenum system with possible catalyst self-poisoning by back-diffusion of product gases during cooldown is a study on the effect of gas composition and temperature on ignition delay. The catalyst was exposed at 293–413 K to gas mixtures representing ammonia dissociations from 0 to 0.9. At 293 K, the ammonia-rich mixture increased the ignition delay to 40 ms, whereas ammonia-lean mixtures increased the delay only slightly. Above 313 K, the effect was no longer noticeable.

Another microreactor that was operated with single injections of 40  $\mu$ L hydrazine onto alumina or rhodium-platinum as support or catalyst and was instrumented to measure the temperature of the catalyst and temperature and composition of the decomposition products by GC had been used by the same group of investigators in France to study the mechanism of hydrazine decomposition on catalysts [1587, 1588]. A similar investigation in the same type of apparatus used a zeolite 5A thermal bed without active metal deposition to study the thermal decomposition of hydrazine at temperatures from 573 to 963 K [1589, 1590]. The products of decomposition were analyzed by GC and the ammonia dissociation fraction plotted as a function of the initial bed temperature. Additional thermal bed materials tested in the same reactor included Pt/Rh wire mesh, CRES spheres (1 mm), Mo spheres (0.7 mm), alumina spheres (0.7 mm), and mol sieve 5A or 13X in the shape of 1.6-mm cylindrical pellets [1572, 1591]. The initial surface area of the alumina was on the order of 100 m<sup>2</sup>/g.

Iridium, rhodium, cobalt, and cobalt/platinum catalysts were prepared by repeated impregnation of  $\gamma$ -alumina and reduction under hydrogen for a nominal active metal content of 9–10% by weight [1592]. Some granules would fracture by the violence of the reaction with hydrazine if they were not properly restrained. To avoid further damage, granular catalysts were then tightly packed between two porous, sintered glass, fritted discs in an evacuated tube. A slug of hydrazine was admitted swiftly by injection with a hypodermic syringe through a rubber septum near the catalyst, and the pressure rise in the adjacent vacuum train was monitored as an indication of catalyst activity. Both the Ir and the Rh catalysts were the most active, with times to equilibration as short as 5 s, but became deactivated after only 10 consecutive tests. Other catalysts were sluggish initially but maintained their low activity for more than 10 tests. Catalyst activity increased with the reduction temperature (reduced at 693, 743, or 793 K under H<sub>2</sub>).

Six different catalysts containing 10% by weight of the six platinum group metals were tested by adding 5 mL anhydrous hydrazine to 0.5 g of catalyst contained in a test

tube with a thermocouple [1593]. Osmium, platinum, rhodium, and palladium had very little activity at room temperature, and the temperature rose only very slowly, until above a threshold temperature the reaction was rapidly self-accelerating. Iridium and ruthenium catalysts were more active and caused intense gas evolution at room temperature. A mixed catalyst containing both ruthenium and rhodium is said to be advantageous for the decomposition of hydrazine blends containing up to 40% water.

In searching for other intermediate species involved in catalytic hydrazine decomposition, a series of ESR experiments were carried out in a flow system, but no free radicals were involved in the reaction, or they were short lived (<10 ms) or remained too close to the catalyst surface [1480]. Furthermore, the catalytic decomposition of hydrazine was not affected by radical scavengers, such as *cis*-1,2,3,6-tetrahydrophthalic acid.

The following mechanism has been proposed by Sayer: the hydrazine molecule exists predominantly in the *gauche* form (Section 2.3), and the two lone electron pairs extend to the same side (e.g., toward the catalyst surface). The lone pairs establish a bond to the catalyst surface by interacting with the unfilled *d* orbitals of the active metal. Hydrazine molecules in the solution may then approach the adsorbed molecule and abstract two hydrogen atoms to form two molecules of ammonia and an adsorbed diazene on the surface. Under the conditions of formation, the *cis*-diazene is formed. The *cis*-diazene can then decompose either by reaction with a neighboring diazene, forming nitrogen that then desorbs or, if it cannot find an adjacent diazene, the diazene decomposes directly to nitrogen and hydrogen.

Active metals deposited on one and the same alumina carrier were compared with regard to their hydrazine decomposition activity in a liquid-phase reactor [1543]. Typical metal loadings were 20% by weight. The relative ranking of the supported catalysts was

and was like that obtained using bulk metal powders instead of supported catalysts. It was suggested that the metal crystal lattice constant of hydrazine decomposition catalysts should be on the order of  $2.6$  to  $2.7 \times 10^{-10}$  m. Compare this to  $2.65 \times 10^{-10}$  m for ruthenium and  $2.71 \times 10^{-10}$  m for iridium. Osmium, despite having the correct geometry ( $2.69 \times 10^{-10}$  m), does not make a good catalyst. Catalysts tested contained 5, 10, and 20 or 30% Ir, 5, 10, and 20% Ru, or 5 and 20% Rh. Catalysts that contained less than 4.5% Ir on  $\text{Al}_2\text{O}_3$  lacked activity for hydrazine decomposition. This was explained by suggesting that at low coverages a large fraction of the metal combines in ionic form with alumina. Iridium was three times more active than ruthenium. In a liquid/solid stirred reactor, 30% hydrazine gave maximum decomposition because the gas bubbles had time to move out of the way and did not surround the particles with a sheath of gas. At higher hydrazine concentrations, the tests became less reproducible. Activation energies for hydrazine (hydrate) decomposition on 11 supported catalysts were derived by repeating the tests at different temperatures. As expected, the addition of ammonia

slowed the rate of hydrazine decomposition. This was most pronounced for the first 1%  $\text{NH}_3$  added to the hydrazine: The rate dropped by 25%. Additional ammonia addition (up to 25% by mass) did not have that much of an effect. Under the conditions of the liquid-phase test, ammonia resulting from hydrazine decomposition accumulated in the propellant and caused the same effect as the initial addition.

With iridium identified as the most active metal, the next question was how to achieve the optimum dispersion of metal on the carrier [1594]. Dispersion is determined by the initial available active surface area of the carrier and the percent of active metal loading. The parameter for evaluating the benefits of dispersion is called *specific catalytic activity* and defined as mol hydrazine decomposed per surface area per unit time and measured in units of  $\text{mol cm}^{-2} \text{s}^{-1}$ . The rate of gas evolution was determined in a stirred reactor at 288 K. In this study, the surface area of alumina was varied from 13 to  $300 \text{ m}^2/\text{g}$ , and the active metal loading was varied from 1.2 to 42% Ir in the finished catalyst. One of the important parameters in this study is the crystallite size. It was assumed that the metal is in the form of equal sized cubes with side length  $d$ , with one face in contact with the support surface

$$d = \frac{5 \times 10^3}{\rho S_{\text{Ir}}}$$

where  $d$  is the side length (cm),  $\rho$  is the density of iridium ( $22.121 \text{ g/cm}^3$ ), and  $S_{\text{Ir}}$  is the active metal surface area as determined from hydrogen chemisorption. The theoretically maximum hydrogen chemisorption, in the case of atomic dispersion of Ir, is  $253 \text{ m}^2/\text{g Ir}$ . In the catalysts prepared here, the specific hydrogen chemisorption decreased from 230 to  $50 \text{ m}^2/\text{g Ir}$  for catalysts containing from 5 to 40 mass-% Ir. The decrease was due to growing crystallite sizes and to crowding of particles. The specific activity of hydrazine decomposition and the active surface area (expressed as  $\text{m}^2/\text{g}$  catalyst) increased initially with the crystallite size  $d$  (1–3 nm). This effect partially compensates for the loss of metal dispersion during the early hours of use of iridium/alumina catalysts at 1300 K in a rocket engine, maintaining the overall activity within acceptable levels. The specific surface area went through a maximum at 33% Ir, confirming the wisdom of early investigators in selecting the active metal loading of Shell 405 catalyst. The results obtained with supported catalysts were then compared to results obtained with iridium black sintered to different crystallite sizes and resulted in similar relationships. This shows that there is no electron transfer between the active metal and the carrier for this type of catalyst.

On the other hand, attempts have been made to explain the increased activity of alumina-supported iridium as not just a physical structural support but instead assuming that electrons exchange between the support and the metal and thus give a more stable quasi-chemical bond. UV spectroscopy, photoelectron XPS and Ir dissolution in acetylacetone were used to determine the nature of the adsorption sites and the state of Ir on supported Ir catalysts [1595]. The catalyst contained 36 mass-% Ir impregnated on  $\gamma\text{-Al}_2\text{O}_3$ . Catalyst attack with acetylacetone allows for the observation of

the dissolution of supported Ir, giving Ir acetylacetonate, which indicates the presence of Ir with a 3+ valence. UV spectroscopy showed that a part of hexachloroiridic acid is reduced during the impregnation of  $\text{Al}_2\text{O}_3$ , giving a chlorinated complex of Ir(III), and the structure of this Ir(III) complex is not destroyed by hydrogen reduction at 673 K (400 °C). The chemical shifts measured in photoelectron XPS spectra confirmed the presence of complexed Ir and demonstrated an electronic interaction between uncomplexed Ir and  $\text{Al}_2\text{O}_3$ .

The kinetics of dilute hydrazine (hydrate) decomposition on catalysts in aqueous solution are like those of hydrogen peroxide decomposition in solution [1596]. Both solutions are sometimes used in fuel cells. In either case, the reaction rate is sometimes diffusion limited.

Although not reversible, hydrazine hydrate is under evaluation as a hydrogen storage medium. Various types of supported metal catalysts for the decomposition of hydrazine hydrate under relatively mild conditions as a source of hydrogen gas were evaluated [1597–1601]. It was not reported how the ammonia in the initially resulting gas mixture was ultimately also decomposed to yield more hydrogen. The complete decomposition of ammonia requires additional energy. Some of these catalysts may be useful for rocket applications.

#### 4.13.2.3 Catalytic Decomposition of Liquid Hydrazine on Metal Oxides and Nitrides

Copper nitride and chromium nitride were tested as decomposition catalysts for hydrazine [58]. Some metal oxides act as catalysts for the decomposition of hydrazine. At higher temperatures, some metal oxides become reduced to the metals. Manganese(IV) oxide is a catalyst for the decomposition of hydrogen peroxide as well as hydrazine. If 100- to 200-mesh manganese dioxide particles are dispersed in dilute aqueous hydrazine solutions at 293–313 K, hydrazine decomposes by heterogeneous reaction [1602]. The kinetic rate can be measured by collecting the nitrogen formed in the reaction. The rate is proportional to the temperature and inversely proportional to the particle size of the manganese dioxide. The overall reaction is of second order. The mechanism seems to be a bimolecular reaction between active sites on the manganese oxide crystals and the hydrazine in solution.

Under most operating conditions in a hydrazine decomposition reactor, nickel oxide would quickly become reduced to a porous nickel structure, but it may last long enough for short rocket propulsion missions. Attempts have been made to alter the catalytic properties of NiO by doping with other oxides [1603].

Macroporous niobium oxynitride was prepared with a specific surface area of  $41\text{ m}^2/\text{g}$  and total pore volume of  $0.43\text{ cm}^3/\text{g}$  and compared to other catalysts in laboratory tests and in a 2-N monopropellant thruster [1604]. The activity of niobium oxynitride in hydrazine decomposition at laboratory scale was lower than that of previously tested tungsten oxynitride. The performance in a 2-N thruster was inferior to that of tungsten oxynitride and Shell 405.

A series of iron nitride catalysts was prepared by a temperature-programmed reaction method and evaluated in a microreactor for hydrazine decomposition [1605]. The catalytic activity of iron nitride was higher than that of iron oxide. The noble-metal-like characteristics of the nitrides might be responsible for the high catalytic activity. The iron nitrides with larger surface areas and smaller particle sizes had higher catalytic activities and  $H_2$  selectivities at high temperatures.

#### 4.14 Combustion of Hydrazine in Air and Oxygen

Even though hydrazine is not a common fuel and is not (yet?) being used to drive combustion engines on Earth at this time, the combustion of hydrazine in air or in combination with other oxidizers constitutes an important chapter in hydrazine chemistry. Many combustion studies have been performed in conjunction with decomposition studies, because hydrazine decomposition constitutes a key step in the reaction preceding combustion. Frequently, the same apparatus is used for both types of experiments [525, 1606].

This section is devoted mainly to the kinetics and mechanism of combustion and the speed with which it proceeds. The gas composition required for flame propagation (the limits of flammability) and the required initiation energy and other safety properties are discussed in Section 8, especially Section 8.3.1. Sometimes the combustion of a hydrazine mixture gets out of hand and results in a detonation. Such detonations are discussed in Section 8.4.2.

This section on combustion is also restricted to the combustion of liquid or vaporized hydrazines requiring an oxidizer. Sometimes the autodecomposition and strand burning of pressed or molten hydrazinium salts is also called “combustion,” but these reactions are discussed elsewhere in *Encyclopedia of Oxidizers*, in the chapter on hydrazinium salts, specifically on the stability of hydrazinium salts.

The same methods described in Section 4.9.1 for measuring decomposition flame speeds can also be used to measure flame speeds in oxidizer-supported combustion flames. Unfortunately, more studies have been performed on hydrazine combustion in oxygen than on the potentially more important combustion of hydrazine in air. Instead of actually measuring flame speeds, some publications discuss just the kinetics of the reaction between oxygen and hydrazine, which may precede the actual combustion. The combustion of hydrazine with other oxidizers is discussed in Section 4.15 following the current section on combustion in air and oxygen. Combustion with other oxidizers, mainly nitrogen oxides, is of practical interest for the use of hydrazine and its derivatives as rocket propellants in bipropellant combinations.

The results obtained during hydrazine combustion in an adiabatic flow reactor with nitrogen dioxide, nitric oxide, and oxygen as oxidizer demonstrated that combustion can occur both with and without prior decomposition of hydrazine, depending on the degree of reactivity of the oxidizer [525].

#### 4.14.1 Combustion in Flow Systems

A thorough investigation of stabilized hydrazine combustion flames in oxygen was conducted in combination with an investigation of hydrazine decomposition flames [1210]. Flames were studied over a wide range of stoichiometric ratios with hydrazine and hydrazine/water mixtures (60.9–97.2%  $\text{N}_2\text{H}_4$  at 423 K). The maxima of flame speeds (570 cm/s for 97.3%  $\text{N}_2\text{H}_4$  and 270 cm/s for 60.9%  $\text{N}_2\text{H}_4$ ) seemed to occur on the oxygen-rich side of the stoichiometric ratio. For comparison, a combustible mixture corresponding to hydrazine decomposition products ( $2\text{NH}_3 + \text{N}_2 + \text{H}_2$ ) was measured at 298 K. Its flame speed was quite low, 160 cm/s, near the stoichiometric ratio. The flame speed of stoichiometric ammonia/oxygen mixtures was even lower (120 cm/s). The difference in flame speeds of hydrazine/oxygen and ammonia/hydrogen/nitrogen/oxygen of identical gross composition must be due to the higher enthalpy of the hydrazine mixture. The data are not inconsistent with a two-stage process in the combustion of hydrazine where decomposition could precede combustion.

The technique used to determine flame speeds was to stabilize the flame on a circular orifice, photograph it, and measure the outline of the reaction cone. The hydrazine had to be pre-vaporized in a 1.2-cm-diameter  $\times$  60-cm-long Pyrex tube heated to 423–443 K. This is usually a very dangerous undertaking, but no flashbacks occurred under carefully controlled experimental conditions. In a 1.4-mm-orifice burner, Reynolds numbers were calculated to obtain an indication as to whether laminar flow could still be possible. In the absence of more accurate data, it was assumed that hydrazine vapor had the same viscosity as oxygen at 423 K ( $2.76 \times 10^{-4} \text{ g cm}^{-1} \text{ s}^{-1} = 2.76 \times 10^{-5} \text{ N s m}^{-2}$ ). With the use of the approximate value, Reynolds numbers of 1450 and 1950 were obtained for hydrazine decomposition and hydrazine plus oxygen combustion flames, respectively. Both flow conditions were thus below 2000, generally considered the transition from laminar to turbulent flow. The flames appeared to be stable to visual observers. As was later shown in closed-vessel combustion studies, the turbulent flame speed is significantly higher than the laminar flame speed.

When comparing calculated flame temperatures and measured flame speeds, the results were found not to be always proportional to each other, as would be predicted from the Zeldovich and Frank-Kamenetskii equation [1382, 1607]. Thus, the temperature plot of hydrazine hydrate/oxygen mixtures falls well below that of ammonia/oxygen mixtures, but the flame speed of 60.9% hydrazine/39.1% water plus oxygen lies well above that of ammonia-oxygen. The discrepancy is believed to be due to thermal conductivity effects. The thermal conductivity of the zone between the hydrazine decomposition front and the combustion front is thought to be increased as a result of hydrogen formed in the decomposition of hydrazine. Measurements of flame propagation, temperature, and flame front thickness in premixed, laminar hydrazine/oxygen/argon flames were correlated with a flame model based on activation energy and chain branching and chain propagation mechanisms and showed good agreement [1389].

Premixed oxygen-hydrazine flames stabilized on a 28-mm burner were found to burn at a flame speed of 2.36 m/s [620, 621].

#### 4.14.2 Combustion in Closed Vessels

The combustion of hydrazine in oxygen or air in a closed vessel may occur with explosive force, and proper precautions must be taken when conducting these experiments. The pressure limits of combustion of hydrazine in closed vessels and in the explosive combustion of hydrazine in oxygen were studied in two cylindrical Pyrex vessels, 4.6 and 2.6 cm in diameter [1608, 1609]. The premixed hydrazine vapor and oxygen were admitted to the preheated (643–813 K) reaction chamber until explosion occurred, and the pressure prior to explosion was recorded. Oxygen-rich mixtures were somewhat more readily ignited than stoichiometric ones. At 809 K and 40% hydrazine, explosions occurred at all pressures above 16 mm Hg total pressure. In the 4.6-cm-diameter vessel, spontaneous explosions would occur at lower pressures than in the 2.6-cm-diameter tube. Argon or nitrogen dilution seemed to lower the pressure limit and aid explosion, whereas helium dilution made it more difficult to ignite the mixtures. An unusual phenomenon was observed in the borderline regime. In mixtures containing more oxygen than the stoichiometric proportions at pressures below the limit for rapid explosion, a yellowish glow appeared after 5–10 s. The delayed ignition could not be found in mixtures containing more than 50% hydrazine. The regime for delayed ignition is restricted by an upper and a lower pressure limit. Various synthetic mixtures representing partially decomposed-combusted hydrazine mixtures were prepared in an effort to explain the delayed reaction. It is believed that the delayed ignition involves the combustion of hydrogen formed by decomposition of hydrazine. In a separate experiment, hydrazine was shown to inhibit the hydrogen + oxygen reaction. Ammonia does not exhibit such inhibition activity. For equimolar mixtures of oxygen and hydrazine, the boundary between slow reaction and explosion in a pressure vs. temperature plot is a straight line, dropping from 693 K/3.2 kPa (420 °C/23 mm Hg) to 761 K/1.6 kPa (488 °C/12 mm Hg) in a Pyrex sphere with 67 mm ID.

Using the same closed vessel and Schlieren photographic technique previously used to study hydrazine vapor decomposition flames, flame speeds in oxygen/hydrazine mixtures at 5.3 kPa (40 mm Hg) and 335 K (144 °F) were measured [1606]. The highest flame speed (4020 cm/s) was observed at a stoichiometric mixture ratio. Above that ratio, it decreased again and approached that of pure hydrazine vapor (1270 cm/s). In hydrazine-rich mixtures no undecomposed hydrazine remained after the combustion. Any hydrazine in excess over the stoichiometric ratio decomposed.

After further refinement of measurement techniques, additional experiments were conducted in a 1-L (61-in.<sup>3</sup>) spherical vessel over the temperature range 690–770 K [1610]. The spontaneous ignition of gaseous mixtures of oxygen and hydrazine was investigated, and emphasis was placed on the direct detection of pre-explosive self-heating in the reacting gas. Very fine thermocouples (made from

0.025 mm Pt and Pt-Rh wires) were used to follow temperature changes and to map temperature-position profiles during oxidation. Unusually among gas-phase oxidations, this spontaneous ignition was clearly thermal in character. Strong self-heating was always observed. In accordance with a conductive theory of heat losses, temperatures were not uniform throughout the reactant but depended on the distance from the vessel center, being greatest at the center and least at the walls. These experiments were aimed at the determination of the boundary line between slow reaction and explosion of equimolar mixtures of hydrazine and oxygen. Between 693 and 763 K these mixtures exploded above 3.2–1.6 kPa (24–12 mm Hg). The rate of temperature increase was measured with ultra-sensitive, fast-response thermocouples. With this technique it was possible to reveal the self-heating that precedes a thermal explosion. The platinum-rhodium thermocouples had to be coated with silica to reduce their catalytic activity. If the logarithm of  $P_{\text{crit}}/T^2$  was plotted against the reciprocal temperature, a straight line was obtained. From the slope of this line an activation energy of  $104 \pm 5 \text{ kJ/mol}$  ( $24.8 \pm 1.2 \text{ kcal/mol}$ ) was calculated for the oxidation of hydrazine.

In similar tests where a low-pressure  $\text{O}_2$ /hydrazine vapor mixture was admitted to a cylindrical quartz chamber (42 mm ID, 165 mm long), a distinct dependence of the autoignition vs. pressure curve on the wall material was noted [1611]. With the clean quartz tube alone, ignition occurred at 2–5 kPa at 830–700 K. Coating the wall with MgO caused the minimum ignition pressure to increase by a factor of 2.5. Coating the wall with  $\text{K}_2\text{B}_4\text{O}_7$  lowered the curve just a little. Admixing 1% dibromotetrafluoroethane, a flame retardant, prior to ignition increased the pressure required for ignition, most likely because the bromine compound traps free radicals (this is why it is used as a fire-extinguishing agent). These three observations were taken as indirect evidence that a branched-chain mechanism is responsible for the ignition of  $\text{O}_2$ /hydrazine mixtures. In addition, the presence of atomic hydrogen in the flame front was proven directly by operating an oxygen/hydrazine burned in the resonator cavity of an EPR spectrometer. The concentration of H atoms was  $5 \times 10^{14} \text{ cm}^{-3}$ , which is much higher than that expected from equilibrium calculations.

#### 4.14.3 Droplet Combustion in Oxygen or Air

Because of the unique exothermic reactions preceding the combustion of hydrazine, the droplet combustion behavior of hydrazine in air differs from that of other fuels, for example, hydrocarbons. A non-linear droplet ignition model has been proposed [1612] that is distinguished from other models by the fact that it exhibits a discontinuity at the ignition temperature. Surprisingly, the air temperature required for ignition increased with decreasing droplet size. Small droplets were said to remain in the evaporative- or kinetic-controlled mode, whereas large droplets were subject to diffusion-controlled combustion. No experimental data exist for hydrazine to support this theory. For hydrocarbons, the dimensionless fuel mass burning rate  $a = (\text{burning velocity}) \times (\text{ra-}$

dus)/diffusivity vs. air temperature curve is S-shaped. For hydrazine, the overall rate of oxidation leading to ignition is assumed to be controlled by a radical-forming hydrazine decomposition reaction.

The droplet combustion of hydrazine alone and in oxygen/nitrogen mixtures with 5.9–21% oxygen was studied [1428–1430]. In addition to experimental work, a complex mathematical model was developed to predict burning rate and flame diameter as a function of droplet diameter and pressure.

Droplet combustion of hydrazine in air and in oxygen was studied in comparison to UDMH and kerosene RP-1 [1439]. Fuel droplets were suspended from a fiber in a quiescent atmosphere of air or oxygen and ignited. Then the combustion was filmed and the droplet size (surface area) measured from the film recordings. The order of increasing burning constant and decreasing droplet lifetime was RP-1, UDMH, and  $N_2H_4$ . The burning rates of all three fuels in oxygen were higher than in air. In a previous study, plots of  $d_2$  versus time gave straight lines for all three fuels, but some deviations were noted for hydrazine. The data resulting from these tests could only be used for a qualitative comparison, and it was very difficult to assign quantitative significance. The results of droplet combustion studies were very difficult to reproduce in other laboratories, and some discrepancies in the literature remained unexplained.

A very thorough study was conducted on the droplet combustion of hydrazine, MMH, and UDMH both in decomposition flames and when burning in an oxidizing environment that provided important new insights into droplet combustion mechanisms [1433, 1434, 1452, 1613]. The major objective of this work was to investigate the combustion characteristics of the hydrazine fuels in the form of liquid drops at atmospheric pressure. Emphasis was placed on high ambient temperature conditions representative of rocket chambers. The mass burning rates (g/s) of hydrazine, MMH, and UDMH as a function of drop diameter, ambient temperature, and ambient oxygen concentration were obtained. Aerozine-50 was also tested. However, a stable burning condition could not be achieved with Aerozine-50 for any test condition [1435, 1455]. The test environment included ambient oxygen concentrations of 0–42 mass-% and ambient gas temperatures of 1660–2530 K. This environment was generated by a flat flame burner fed with mixtures of nitrogen, hydrogen, carbon monoxide, and oxygen. The fuel droplets were then suspended from a quartz fiber, or larger droplets were simulated with porous spheres. The same apparatus was used for decomposition flame studies without oxygen supply (Section 4.15.1.2) and combustion flame studies. In the oxidation studies, all three fuels showed a flame with two distinct zones of luminosity. Because decomposition flames were non-luminous, it has been suggested that both zones were the result of oxidation reactions. A hybrid combustion model was formulated as opposed to a bipropellant combustion model, which assumes simple evaporation in a diffusion-limited environment. In the hybrid mode, the monopropellant decomposition of the fuel prior to combustion is taken into consideration. The results indicated that fuels capable of hybrid combustion showed increasing burning rate with increasing ambient oxygen concentration (Figure 50), diameter (Figure 51), and

**Figure 50:** Hydrazine droplet burning rates at various ambient oxygen concentrations. (Reproduced and modified from [1613].)

ambient temperature. Similar graphs for MMH instead of hydrazine will be shown in the chapter on methylhydrazine.

As the effect of the monopropellant decomposition zone became more important (e.g., in the sequence UDMH, MMH, hydrazine), the burning rate was less sensitive to variations in ambient conditions. In the presence of monopropellant behavior, the burning rate was found to be proportional to the square of the droplet diameter. Of the three fuels tested, hydrazine exhibited most distinctly hybrid combustion with all droplet sizes, whereas MMH and UDMH showed this behavior only with very large droplets.

Comparison of the mass burning rate curves of hydrazine and MMH depending on oxygen concentration reveals that the hydrazine curves (Figure 50) are much flatter

**Figure 51:** Hydrazine droplet burning rate in an oxidizing atmosphere. (Reproduced and modified from [1613].)

(less dependent on oxygen) than the MMH curves (Figure 32 in the chapter “Methylhydrazine”). Droplet life studies are useful for designing injectors for bipropellant rocket engines, in particular those employing hypergolic oxidizers. Additional droplet combustion studies of hydrazine and methylhydrazine combustion in hypergolic oxidizer atmospheres are discussed in Section 4.15.1.2.

A two-step combustion process, consisting of monopropellant burning followed by bipropellant (i.e., two-reactant) burning, was modeled and burning-rate variations for reactions with large activation energies were predicted [1614]. The original reactant, vapor from a liquid droplet, decomposes into a fuel that burns with oxidant in the surrounding oxidizer-rich atmosphere. Complete responses of the evaporation rate of the droplet to the Damköhler numbers  $D_1$ ,  $D_2$  of the two reactions were determined within the limit of large activation energies. Conditions under which the re-

sponse was monotonic or multi-valued (thereby exhibiting auto-ignition and auto-extinction) were identified. The efficacy of activation-energy asymptotics in dealing with the strongly non-linear Arrhenius term of reactive fluid mechanics was thus demonstrated.

#### 4.14.4 Liquid Strand/Open Pool Burning of Hydrazine in Oxidizing Atmospheres

The strand burning technique as applied to monopropellant decomposition of hydrazine in the absence of an oxidizing atmosphere was already discussed in Section 4.10.1. The same tests repeated in air or oxygen would typically give higher regression rates and would allow one to observe the dual flame zones that were discovered previously for droplet combustion. Whereas strands with  $L/D$  larger than 1 are typically used for laboratory studies of combustion kinetics, open-air burning tests in pits or pans with  $L/D$  smaller than 1 are typically done to assess the fire hazard of burning fuel spills and to test methods for extinguishing burning propellant spills.

The addition of ethanol to hydrazine reduced the strand burning rate of hydrazine in air [1615]. In a 0.99-cm-diameter tube, the addition of 2, 8, or 14.4% ethanol decreased the burning rate from 0.032 g/s to 0.022, 0.020, or 0.012 g/s, respectively. The burning rate of hydrazine depends on the tube diameter, the flame consuming 0.026, 0.032, 0.052, or 0.083 g/s in 0.75-, 0.99-, 1.37-, or 1.81-cm-diameter tubes, respectively. The diameter dependence of the burning rate was in agreement with Spalding's formula. In an  $N_2O_4/NO_2$  atmosphere, hydrazine burned even faster, 0.083 g/s in a 1.37-cm-diameter tube. Measurements of the horizontal and vertical flame temperature profile of flames in air showed maximum temperatures near 1400 K, much hotter than ethanol flames.

If the hydrazine liquid is gelled prior to forming it into a strand, convection in the liquid is suppressed, and slightly different strand burning rates, such as those in gaseous oxygen, are obtained [1616]. The results indicated that the decomposition rate is a function of the heat transfer from the flame to the liquid surface. The limiting burning rate of hydrazine gel was roughly proportional to the pressure in the combustion bomb. If the oxygen was blown over the sample, such as in a hybrid rocket, the burning rate was also proportional to the injection velocity of the oxidizer.

#### 4.15 Combustion of Hydrazine with Other Oxidizers

While the combustion reactions of hydrazine(s) with oxygen or ozone have been thoroughly studied, they may not necessarily be the practically most important combustion reactions. Other oxidizers, such as NTO, are more frequently used in combination with hydrazine fuels in rocket engines. Therefore, it is important to investigate reactions of nitrogen dioxide and NTO with hydrazines.

#### 4.15.1 Combustion of Hydrazine with Nitrogen Dioxide

The combustion of hydrazine with nitrogen dioxide (or, depending on the initial temperature, NTO) has undergone thorough investigation because of its practical importance as a hypergolic rocket propellant combination. Actually, NTO was not used with undiluted hydrazine in any bipropellant rockets for a long time because the cooling could initially not be managed safely. Because of the limitations in the use of pure hydrazine for regenerative cooling, a 50:50 mixture of hydrazine and UDMH called Aerozine-50 (Ae-50) had been used in all of the APOLLO and GEMINI missions and numerous other launch vehicles and upper stages. In this mixture, the interaction between nitrogen dioxide and hydrazine constitutes a key reaction leading to the desired hypergolic ignition. This reaction is considerably more vigorous than that of nitrogen dioxide with methylhydrazines. As a matter of fact, the reaction is so vigorous that it is difficult to obtain a reaction between liquid propellants. At the moment of first contact between NTO and hydrazine the reaction at the interface of the droplets is so fast and so vigorous that the droplets are driven apart, thus preventing further reaction going to completeness (reactive stream separation.) Numerous investigations deal with this problem and try to identify intermediates. Some of the kinetics and theories regarding possible intermediates in  $\text{N}_2\text{O}_4 + \text{N}_2\text{H}_4$  reactions were discussed in Section 3.1.7 (wet reactions in solution and vapor reactions) and rocket engine studies will be described in a future *Encyclopedia of Hypergolic Bipropellant Combinations*, in the chapter “Hypergolic Combinations with Nitrogen Oxides.”

##### 4.15.1.1 Vapor-Phase Reaction Kinetics of $\text{N}_2\text{O}_4/\text{NO}_2/\text{N}_2\text{H}_4$ Reactions

The reaction of nitrogen dioxide and hydrazine exhibited two distinct steps of greatly different rates [525, 1617]. The first step took place very rapidly and consisted of a reduction of the nitrogen dioxide to nitric oxide. This reaction was then followed by a second, slower one, the reduction of nitric oxide to nitrogen. Each of these steps involved several interconnected reactions. The kinetic study was conducted in an adiabatic flow reactor, like the one used for hydrazine decomposition. Rapid mixing of the highly diluted ( $10^{-7}$  mol/cm<sup>3</sup>) reactants was achieved in the inlet portion. The temperature profile along the 120-cm (4-ft)-long reaction zone was then measured as a function of initial parameters. The reaction of nitrogen dioxide and hydrazine produced a stepwise temperature profile with two reactions separated by a plateau of nearly constant temperature. The two steps are used to subdivide Table 64. The step I reaction

proceeded at a rate greater than, and an overall activation energy less than, that for hydrazine decomposition. It was concluded that this reaction occurred without dependence on hydrazine decomposition or breaking of the N—N bond (the activation energy for which would have been 251 kJ/mol = 60 kcal/mol) [525].

**Table 64:** Summary of postulated reaction mechanisms.

| $\text{N}_2\text{H}_4 + \text{NO}_2$ (Step I)                                                | $\text{N}_2\text{H}_4 + \text{NO}_2$ and<br>$\text{N}_2\text{H}_4 + \text{NO}$ (Step II)        | $\text{N}_2\text{H}_4 + \text{O}_2$                                                          |
|----------------------------------------------------------------------------------------------|-------------------------------------------------------------------------------------------------|----------------------------------------------------------------------------------------------|
| <i>Initiation</i>                                                                            |                                                                                                 |                                                                                              |
| $\text{N}_2\text{H}_4 + \text{NO}_2 \rightarrow \text{N}_2\text{H}_3 + \text{HONO}$ (1)      | $\text{N}_2\text{H}_4 \rightarrow \text{M}^a \rightarrow \text{NH}_2 + \text{NH}_2$ (9)         | $\text{N}_2\text{H}_4 \rightarrow \text{M} \rightarrow \text{NH}_2 + \text{NH}_2$ (9)        |
| <i>Branching</i>                                                                             |                                                                                                 |                                                                                              |
|                                                                                              | $\text{N}_2\text{H}_3 \rightarrow \text{M} \rightarrow \text{NH}_2 + \text{NH}$ (10)            | $\text{N}_2\text{H}_3 \rightarrow \text{M} \rightarrow \text{NH}_2 + \text{NH}$ (10)         |
| <i>Propagation</i>                                                                           |                                                                                                 |                                                                                              |
| $\text{N}_2\text{H}_4 + \text{OH} \rightarrow \text{N}_2\text{H}_3 + \text{H}_2\text{O}$ (2) | $\text{N}_2\text{H}_4 + \text{NH}_2 \rightarrow \text{N}_2\text{H}_3 + \text{NH}_3$ (11)        | $\text{NH}_2 + \text{O}_2 \rightarrow \text{HNO} + \text{OH}$ (19)                           |
| $\text{N}_2\text{H}_3 + \text{NO}_2 \rightarrow \text{N}_2\text{H}_2 + \text{HONO}$ (3)      | $\text{N}_2\text{H}_3 + \text{NH}_2 \rightarrow \text{N}_2\text{H}_2 + \text{NH}_3$ (12)        | $\text{N}_2\text{H}_3 + \text{O}_2 \rightarrow \text{NH}_2\text{NO} + \text{OH}$ (20)        |
| $\text{N}_2\text{H}_3 + \text{OH} \rightarrow \text{N}_2\text{H}_2 + \text{H}_2\text{O}$ (4) | $\text{NO} + \text{NH}_2 \rightarrow \text{NH}_2\text{NO}$ (13)                                 | $\text{N}_2\text{H}_4 + \text{OH} \rightarrow \text{N}_2\text{H}_3 + \text{H}_2\text{O}$ (2) |
| $\text{HONO} \rightarrow \text{OH} + \text{NO}$ (5)                                          | $\text{NO} + \text{NH} \rightarrow \text{N}_2 + \text{OH}$ (14)                                 | $\text{N}_2\text{H}_3 + \text{OH} \rightarrow \text{N}_2\text{H}_2 + \text{H}_2\text{O}$ (4) |
| $\text{H}_2 + \text{OH} \rightarrow \text{H}_2\text{O} + \text{H}$ (6)                       | $\text{N}_2\text{H}_4 + \text{OH} \rightarrow \text{N}_2\text{H}_3 + \text{H}_2\text{O}$ (2)    | $\text{N}_2\text{H}_4 + \text{NH}_2 \rightarrow \text{N}_2\text{H}_3 + \text{NH}_3$ (11)     |
| $\text{NO}_2 + \text{H} \rightarrow \text{HONO}$ (7)                                         | $\text{N}_2\text{H}_3 \rightarrow \text{M} \rightarrow \text{N}_2 + \text{H}_2 + \text{H}$ (15) |                                                                                              |
|                                                                                              | $\text{NH}_2\text{NO} \rightarrow \text{HN}_2 + \text{OH}$ (16)                                 |                                                                                              |
|                                                                                              | $\text{HN}_2 \rightarrow \text{N}_2 + \text{H}$ (17)                                            |                                                                                              |
| <i>Termination</i>                                                                           |                                                                                                 |                                                                                              |
| $\text{N}_2\text{H}_2 \rightarrow \text{N}_2 + \text{H}_2$ (8)                               | $\text{N}_2\text{H}_2 \rightarrow \text{N}_2 + \text{H}_2$ (8)                                  |                                                                                              |
|                                                                                              | $\text{NH}_2\text{NO} \rightarrow \text{H}_2\text{O} + \text{N}_2$ (18)                         | $\text{NH}_2\text{NO} \rightarrow \text{H}_2\text{O} + \text{N}_2$ (18)                      |
|                                                                                              |                                                                                                 | $\text{OH} + \text{NO} \rightarrow \text{HONO}$ (21)                                         |
|                                                                                              |                                                                                                 | $\text{HNO} + \text{OH} \rightarrow \text{H}_2\text{O} + \text{NO}$ (22)                     |

<sup>a</sup> **M** symbolizes the wall of the reaction vessel acting as third body.

Data source: [525]

The global rate constant for step I can be expressed as

$$k = 10^{15.83 \pm 0.58} e^{-\frac{26700 \pm 1100}{RT}}$$

The second step of the reaction of nitrogen dioxide and hydrazine

proceeded at a rate comparable to the reaction of hydrazine and nitric oxide. Under these conditions, approximately 15% of the hydrazine decomposed before it reacted with NO, and the decomposition products hydrogen and ammonia did not react with NO under the conditions of the adiabatic reactor. The rate constant for step II is

$$k = 10^{10.17 \pm 0.55} e^{-\frac{39600 \pm 2600}{RT}}$$

compared to that for the  $\text{NO} + \text{N}_2\text{H}_4$  reaction

$$k = 10^{11.48 \pm 0.32} e^{-\frac{45400 \pm 1500}{RT}}$$

The Arrhenius parameters were compared assuming a first-order dependency on the hydrazine concentration in both cases. Actually, the rate of hydrazine consumption in

mixture with NO in the adiabatic flow reactor was found to be proportional to only the 0.75<sup>th</sup> power of the hydrazine concentration. Table 64 gives a summary of the postulated reaction mechanism, in which the abstraction of hydrogen by nitrogen dioxide and hydroxyl radicals plays a key role.

One of the suspected explosive intermediates in the reaction of  $\text{N}_2\text{O}_4$  and  $\text{N}_2\text{H}_4$  is hydrogen azide and its hydrazinium salt. Hydrogen azide was detected in the gas phase when  $\text{N}_2\text{O}_4$  vapor was passed over condensed  $\text{N}_2\text{H}_4$  and analyzed by mass spectrometer as indicated by peaks at  $m/e = 43$  and  $42$  [613]. In a different test, the reactants were diluted in tetrachloromethane and then poured together. Azide also forms in aqueous solutions of hydrazine and nitrate ions, during storage of aqueous hydrazinium nitrate solutions, and solutions of hydrazinium nitrate in hydrazine.

The conservation equations in the boundary layer form have been solved for coaxial flowing and reacting streams of hydrazine and nitrogen dioxide [1618]. The model for the hypothetical burner was patterned after the Burke-Schumann approach, for axially symmetric flow in cylinder coordinates, but the new model included substantially more computing power. The oxidizer was assumed to be introduced in the core and surrounded by an excess of fuel vapor. Detailed chemical kinetics and transport equations were used in the simulation, which included 22 species and 151 reactions. Reaction intermediates receiving special attention were nitrous acid HONO, hyponitrous acid HNO, and hydrogen peroxide. A gradual buildup of peroxide in the low-temperature fuel-rich region of the flame is thought to play an important role in the overall mechanism.

To construct a  $\text{N}_2\text{O}_4/\text{N}_2\text{H}_4$  combustion model that is useful for bipropellant thruster simulation, the literature concerned with elementary  $\text{N}_2\text{O}_4/\text{N}_2\text{H}_4$  reactions was surveyed in detail [1619]. A total of 245 reactions were found in 16 available studies that needed a common denominator for future use in a computer model.

A hydrazine and NTO combustion model that is useful for bipropellant thruster CFD simulation was developed by extracting appropriate elementary reactions from a detailed kinetic reaction model developed by Ohminami and Ogawa [1619]. The reduced hydrazine and NTO combustion model was composed of 61 extracted reactions with 23 chemical species and was coincident with the original detailed kinetic reaction model in terms of combustion gas temperatures and ignition delay times over the oxidizer and fuel mass ratio (O/F) range from 0.82 to 1.84 [1620]. The simulated combustion gas temperatures agreed with the adiabatic flame temperatures, and the simulated ignition delay time at  $\text{O/F} = 1.2$  was consistent with the literature value.

Hydrazine and nitrogen dioxide co-flowing plane jets and coaxial jets were simulated to explore the double flame structures in hypergolic  $\text{N}_2\text{O}_4 + \text{N}_2\text{H}_4$  bipropellant thrusters [1621]. The Navier-Stokes equations with a detailed chemical kinetics mechanism were solved in a manner of direct numerical simulation to reveal the interaction between fluid dynamics and the distinct chemical reaction, i.e., hydrogen abstraction by  $\text{NO}_2$  and the thermal decomposition of  $\text{N}_2\text{H}_4$ . The flames are uniquely composed of two types of flame, a diffusion flame and a decomposition flame. The diffusion flame

came from the oxidation by  $\text{NO}_2$ . The decomposition flame was caused by the heat transfer from the diffusion flame and a high rate of heat release from the thermal decomposition of  $\text{N}_2\text{H}_4$ .

#### 4.15.1.2 Hydrazine Droplet Combustion in an $\text{N}_2\text{O}_4$ Atmosphere

The combination of NTO and hydrazine(s) constitutes a very powerful rocket propellant. Because  $\text{N}_2\text{O}_4$  vaporizes at a lower temperature than fuel, the condition near the injector of an  $\text{N}_2\text{O}_4$ /hydrazine fuel rocket is usually that of hydrazine (or MMH or UDMH) droplets burning in an  $\text{N}_2\text{O}_4$  or  $\text{NO}_2$  gas atmosphere. Many experimental and theoretical studies have been conducted to study the hydrazine droplet combustion and unsteady phenomena associated therewith.

In a study on hydrazine droplets suspended from a thermocouple and burning in  $\text{N}_2\text{O}_4$  vapor, it was found that the hydrazine droplet temperature remained at the boiling point during steady-state burning [1622–1624].

The effect of additives on the burning rate of hydrazine droplets burning in dinitrogen tetroxide vapor was measured and an attempt was made to relate these effects to rocket engine (in)stability [1625–1628]. This depended on a basic understanding of the hydrazine/dinitrogen tetroxide flame structure, using this knowledge to select effective additives, and then measuring the effectiveness of these additives in changing the hydrazine burning rate. The application of this work to stability control then involved the computation of additive distillation and inclusion of this effect in a steady-state combustion computer program. The resulting combustion profiles with and without additives were compared, and stability changes were identified.

It was also found that (in analogy to hydrazine combustion in oxygen) hydrazine droplets burned in two distinctly different flame regions: an inner decomposition flame and an outer oxidation flame [1629]. Hydrazine burned much faster in  $\text{N}_2\text{O}_4$  than in any other oxidizer. Ignition of the hydrazine droplets was preceded by the formation of a milky film on the droplet (ammonium nitrate?), followed by the initiation of a vapor-phase reaction. Occasionally droplet shattering was observed, but this occurred at random and could not be correlated to any test parameter.

The theoretical monopropellant decomposition unit area burning rate for hydrazine itself was calculated as  $140 \text{ g m}^{-2} \text{ s}^{-1}$  ( $2.86 \times 10^{-2} \text{ lb ft}^{-2} \text{ s}^{-1}$ ). This value agrees within 2% of that reported based on experimental data [1431, 1432]. When plotting the unit area burning rate as a function of oxidizer ( $\text{N}_2\text{O}_4$ ) concentration  $O_x$ , the intercept at  $O_x = 0$  corresponded to the monopropellant burning rate.

The effect of additives on the droplet burning rate of hydrazine in  $\text{N}_2\text{O}_4$  vapor was studied [1626]. Ammonium nitrate was tested as an additive [1628]. It was found that some of the additives would cause hydrazine droplets to break up, thereby leading to increased rates of vaporization and possibly shorter characteristic lengths in rocket engines.

A mathematical model representing two phases, liquid and gas, was developed for the steady-state combustion of a single hydrazine droplet in an NTO atmo-

sphere [1630]. The spherically symmetric model generates a two-point boundary value problem in one dimension (the spherical coordinate), which was solved by Newton's method with an adaptive gridding technique. The burning rate of the droplet was obtained as an eigenvalue to eliminate the uncertainty or complexity of evaporation and condensation rate laws. The resulting temperature profile exhibited a two-zone flame structure, which was like that observed in an experiment reported in the literature.

#### 4.15.2 Combustion of Hydrazine with Nitric Oxide or Nitrous Oxide

One proposed reaction mechanism for the reaction of nitric oxide with hydrazine was already shown in Table 64. In this mechanism as well as in the oxidation with nitrogen dioxide or oxygen, nitrosamine  $\text{H}_2\text{NNO}$  is believed to take part as an intermediate in most of the reactions. However, there has been no attempt to identify it in the reacting mixture by drawing samples into a mass spectrometer. This was achieved only in a later study on the elementary steps for the formation and consumption of nitric oxide in the H/N/O system [543]. In the  $\text{NO}/\text{O}_2/\text{N}_2\text{H}_4$  system,  $\text{NO}_2$  formation took place in two steps: The first rapid reaction of NO and  $\text{N}_2\text{H}_4$  proceeded in the presence of  $\text{O}_2$  and yielded a relatively stable (yet unidentified) species. This reaction was followed by a slower reaction, which produced  $\text{NO}_2$  [1631].

In one of the earliest studies on hydrazine decomposition and combustion flames, the formation of  $\text{N}_2$  in the reaction of hydrazine with nitric oxide was observed [1228]. Lacking additional information and modern instrumentation, it was postulated that hydrazyl radicals participate in hydrazine decomposition:

This assumption was later assailed [1200], but all data available now indicate that Bamford was indeed right with his early prediction. The only question is whether  $\bullet\text{N}_2\text{H}_3$  is involved in the rate-determining step.

The temperature-pressure-composition limits for the initiation of thermal explosions in nitric oxide/hydrazine mixtures have been determined in a silica vessel between 613 and 923 K [1632]. In general, nitric oxide is not as active an oxidizer in combustion systems (hydrocarbons,  $\text{H}_2$ , CO) like oxygen itself. However, with ammonia or hydrazine as fuel this relation is reversed. Nitric oxide/hydrazine mixtures exploded somewhat more readily than the corresponding oxygen/hydrazine mixtures. The minimum ignition temperature for stoichiometric oxygen, nitric oxide, or nitrous oxide mixtures with hydrazine at 6.6 kPa (50 mm Hg) total pressure were 608, 673, or 943 K, respectively. Surprisingly, nitrous oxide ( $\text{N}_2\text{O}$ ) acted more like a diluent than an oxidizer, but once the reaction was started, it was consumed in the combustion. One way to compare the action of the two gases is to plot the hydrazine partial pressure in the total pressure/composition diagram. Whereas it underwent a minimum and then increased with hydrazine concentration (indicating reaction) in the  $\text{NO}/\text{N}_2\text{H}_4$  system,

the graph with  $\text{N}_2\text{O}$  showed the hydrazine partial pressure to be a straight line parallel to the abscissa, indicating a mere dilution effect of  $\text{N}_2\text{O}$ .

Although both nitric oxide and nitrous oxide have positive heats of formation (as does hydrazine), the flame speed in mixtures of hydrazine vapor with these oxidizers did not exceed that of oxygen/hydrazine mixtures [1606]. At 5.3 kPa (40 mm Hg) pressure and 335 K, the maximum flame speed with NO was 31.5 cm/s and 24 m/s with  $\text{N}_2\text{O}$  at a stoichiometric mixture ratio.

In addition to the flame speeds and flammability limits of the binary nitric oxide/hydrazine and nitrous oxide/hydrazine mixtures, ternary nitric oxide/nitrous oxide/hydrazine mixtures have also been investigated at sub-atmospheric pressures [1633]. The maximum burning velocity was that of a fuel-rich binary NO/ $\text{N}_2\text{H}_4$  mixture with no  $\text{N}_2\text{O}$  present. This is different from the behavior in the NO/ $\text{N}_2\text{O}$ / $\text{NH}_3$  system, where the flame speeds of ternary mixtures were faster than those of either binary system. With hydrazine as a fuel, nitric oxide supported combustion better than did nitrous oxide. With the use of hydrogen gas as a fuel, the relative activity of the two oxides was reversed. Nitric oxide in the hydrogen flame tended to act both as an inhibitor and as an oxidant. A flame speed of 3600 cm/s was measured in a fuel-rich (50%  $\text{N}_2\text{H}_4$ ) mixture with NO from which  $\text{N}_2\text{O}$  was absent. In lean ternary mixtures, the two oxidizers enhanced each other's activity.

## 5 Materials of Construction for Hydrazine

Many summaries and survey papers on material compatibility with hydrazine have been published, of which the following few may serve as starting points for further study: [1634–1638]. Many of these summaries, in particular [1639, 1640], are already obsolete and now only of historical value to the spacecraft designer. Some of these summaries deal not only with hydrazine itself, but also with some of its methyl derivatives.

An excellent design handbook, but only for privileged readers eligible to obtain copies, is [1641]. It contains information on hydrazine liquid and hot decomposition product materials' compatibility and the effects of temperature, hydrazine purity, and passivation techniques on compatibility. Because a complete compilation of all material compatibility data with hydrazine fuels would easily fill another book equal in size to this one, a compromise format had to be sought in presenting material compatibility data here.

Even after published data are located, there are often serious questions about the reliability of these data and their applicability to the current material selection question at hand. The results obtained by different researchers vary with the method and the purity of the hydrazine used. Often materials that are acceptable for use in bipropellant rocket tanks may not be acceptable for monopropellant systems with their increased purity requirements. It is very regrettable that many of the early publications

on hydrazine material compatibility dating to the 1950s and 1960s have simply copied data (often unreliable data) indiscriminately from each other, thus propagating misinformation, and these publications should be ignored. An example is [1642]. Many of these reports, such as [1643], are concerned only with bipropellant use of hydrazines. This Battelle DMIC report is one of the most frequently misquoted summary reports in this category, and its conclusions need to be carefully scrutinized and verified before designing any system, in particular a monopropellant system. Many of the materials listed in this Battelle DMIC report were later shown to be unacceptable for hydrazine monopropellant systems.

Another design guidebook on material compatibility with space storable propellants was [1644]. It contained sections on hydrazine, MMH, and a hydrazine/hydrazinium nitrate blend. In addition, it contained material compatibility information on other liquid rocket propellants (diborane, NTO, liquid fluorine, oxygen difluoride, FLOX). The hydrazine section of this design guidebook was reprinted as an appendix to a JPL report published in the same year [1635], but most of the information therein needs updating.

The present book unfortunately is no exception in relying on data obtained by other sources because it is only a summary (albeit a critical summary) of data published by other principal investigators. Data on material compatibility research with hydrazines generated by the author during the author's experimental chemistry career in the US aerospace industry remain company-proprietary data and have not been released for general distribution.

**Sources of Information.** The most methodical way to organize the vast amount of data on material compatibility with hydrazine(s) would be in a database with cross-referencing, possibly distributed to interested parties on a CD-ROM disc or available for online search. Initial modest attempts have been made at various places in this direction, but only for company internal use and not intended for general distribution. Most of the references retrievable by public services prior to 1994 were already incorporated into the second edition of the hydrazine book for the convenience of the reader. References to the other online databases may help readers in updating their files and obtaining even more recent information, although the URLs or the public availability of databases may change from time to time between the date of publication of this book and the date when the reader is logging on the Internet. It has been common practice to annotate each URL listing with the note "accessed on ... (date)," but this has not been done consistently for the current book.

From time to time, entire conferences have been devoted to the topic of propellant and hydrazine material compatibility. Proceedings from such conferences are a good source of information. For several years in a row, a Working Group for Materials Compatibility of Storable Propellants convened in conjunction with other JANNAF meetings and was a very useful forum for exchange of information. It is regrettable that no comparable organization exists at this time. There should be at least a bulletin board on the Internet where compatibility issues and contamination incidents caused by in-

compatibility could be posted and incompatible materials can be red flagged. Material compatibility issues with rocket propellants are often discussed at JANNAF Propellant Development and Characterization meetings, but the proceedings are not available to the general public. Additional information used to be available from the manufacturers of hydrazines, sometimes in the form of product data sheets for hydrazine [1645], but this is no longer the case. Product information published on company web sites is sparse and rarely goes beyond the most fundamental physical properties like freezing point and boiling point.

**Rating Systems.** For the most common materials of construction, compatibility ratings are often given only in qualitative terms. There exists no standardized rating system for the compatibility of materials. Trying to obtain a material compatibility rating for a material of construction is not like consulting your personal stockbroker and financial advisor for a Moody's bond rating system (e.g., AAA, BB+) that is widely accepted in the financial community. At the other end of the compatibility spectrum, some flagrant cases of material incompatibility and the resulting system malfunctions are cited here as warning examples of the lack of reliability of information found in the literature. It is difficult to give a general stamp of approval for materials of construction without knowing the exact circumstances of the intended application. In many cases, a certain material compatibility test will have to be performed under simulated conditions to make sure that the questionable material is suitable for the intended conditions of hydrazine service (temperature, duration). Many materials have been rated for hydrazine hydrate solution use, but exposing them to anhydrous hydrazine is a totally different corrosive and more reactive environment.

Some chemical suppliers have posted material compatibility data banks on the Internet, but these can only provide crude and often erroneous compatibility information. One example with misleading information is the Cole Parmer databank, which erroneously lists polyacetal resins (Delrin) as compatible ("Good") with hydrazine. Delrin dissolves in anhydrous hydrazine. Another blatant mistake is the rating of Kynar 460 as "Excellent" when it actually catalyzes thermal decomposition of hydrazine between 388 and 413 K and in one instance caused the destruction of a test apparatus [1646].

## 5.1 Compatibility with Liquid Hydrazines

A major concern to the designer of hydrazine systems is the compatibility of wetted components with hydrazines in the liquid phase during storage and transfer. In other applications, such as in the design of distillation columns for the production of anhydrous hydrazine, compatibility with hydrazine vapors must also be known.

For structural applications in tanks, lines, valves, or surface tension propellant management devices the metals most commonly selected are the alloys of titanium or stainless steels. Such alloys have been used in many flight systems with anhydrous

hydrazine such as the MARINER, VOYAGER, VIKING, CASSINI, and NEW HORIZONS space probes and many satellites in Earth's orbit. Fairly complete compatibility data are available for the following alloys in anhydrous hydrazine for periods of 4 years and beyond: titanium 6Al-4V, aluminum Al-6061, Al-2014, and Al-2219, and the stainless steels CRES-301, CRES-304, CRES-304L, and CRES-321. All these metals when immersed in hydrazine showed corrosion rates much lower than  $25\mu\text{m}/\text{year}$ . There is no evidence from published data that any of these metals in contact with propellant-grade hydrazine are subject to stress-corrosion cracking (SCC), intergranular corrosion, embrittlement, or shock sensitivity. Individual sections will discuss titanium alloys, stainless steels, and aluminum alloys on the following pages.

**Material Compatibility Quantified.** To compare the suitability of candidate materials of construction for a given application, it would be best to have a figure of merit that includes all possible parameters. Depending on the application, each of the properties will receive a different weighting factor if one wants to evaluate different candidate materials for a given application and perform a systematic evaluation matrix.

One of the many variables is the purity of the hydrazine. When a special high-purity hydrazine was developed for the VIKING mission to Mars, initially there was concern that removal of trace contaminants might change the corrosion behavior of propellant-grade hydrazine. Aniline that was removed from the VIKING-grade hydrazine might have acted as a corrosion inhibitor, just like it inhibits the activity of some catalysts. The purified material turned out to be less corrosive than the propellant-grade material, but the difference was only minor [110, 241]. At higher temperature (343 K), the differences between the three metals were less pronounced, and the rate exponents were very similar.

**History of Hydrazine Material Compatibility Testing.** One of the leading organizations in hydrazine material compatibility research is the Jet Propulsion Laboratory managed by the California Institute of Technology in Pasadena, CA. A Phase I program was intended only as a screening program and involved 51 samples in hydrazine, a 76% hydrazine/24% hydrazinium nitrate blend, and a 50:50 hydrazine/UDMH blend [1647]. A very comprehensive material compatibility program followed in 1970. Initially more than 700 test ampoules (including some with MMH or NTO) were placed in long-term storage testing at 316 K (110 °F). Intermediate results after up to 5 years in storage at 316 K (110 °F), based on the opening of 108 ampoules containing hydrazine, 12 ampoules containing a hydrazine/hydrazinium nitrate blend, and 4 ampoules containing MMH, were reported [1638]. At that time (1976), 578 specimen capsules remained in active test, and some were scheduled to remain in testing for a full 10 years.

In preparation for the tests, the glass ampoules were cleaned, loaded with a specimen, filled with propellant, cooled in liquid nitrogen, evacuated, and hermetically sealed with a blow torch. Most test specimens were in the shape of flat rectangular coupons, typically 1.27 cm wide, 7.62 cm long, and 0.076 cm thick. They were typically half submerged in the liquid propellant. The top half was exposed

to vapor and condensate only. Each constant temperature test bay was equipped with a circular rotatable storage rack (a lazy susan type of a carousel arrangement) with a capability to hold over 900 test capsules. The internal ampoule pressure was intended to be measured by externally mounted strain gauges forming part of a Wheatstone bridge. Unfortunately, nearly all strain gauges failed after only a few years of testing. Subsequent measurements of the amount of hydrazine decomposition thus had to rely on collecting the gases by remotely opening the capsule after it was removed from the constant-temperature test bay. This gave only one terminal data point for gas evolution. The decomposition gases were analyzed by GC for  $\text{NH}_3$ ,  $\text{H}_2\text{O}$ , MMH, and UDMH. Aniline was determined by UV absorption. Metals leached from the specimens were analyzed by atomic absorption. Chloride, fluoride, and carbon dioxide were also analyzed on selected samples. Unfortunately, many samples had residual CFC-113 (Freon-TF) from a cleaning process included with the hydrazine at the moment the ampoules were sealed, resulting in high chloride and fluoride concentrations in the off-loaded hydrazine and accelerated corrosion of many metal specimens. This invalidated many of these test results. Even titanium samples were coated with a layer of corrosion products. It is still possible to derive some useful information from the JPL data despite the unfortunate halide contamination. When tabulating results from JPL tests, one should sort the database by the halide concentration and eliminate all those with higher than MIL-SPEC levels of chloride (counting all fluoride as chloride).

Besides MIL-SPEC monopropellant-grade hydrazine, VIKING-grade hydrazine, MMH, and a 24% hydrazinium nitrate/hydrazine mixture have been used for many material compatibility tests at JPL. The effect of carbon dioxide contamination on CRES-303, CRES-304L, and CRES-347 corrosion in hydrazine after 15, 30, 45, and 91 d was the subject of a special series of tests. Hydrazine spiked with 27, 52, 90, and 230 ppm  $\text{CO}_2$  suffered progressively worse decomposition with increasing  $\text{CO}_2$  content. The amount of iron leached from the steel also increased drastically, up to 40 ppm Fe leached from CRES-303 within 91 d in hydrazine doped with 230 ppm  $\text{CO}_2$ . The lowest level of hydrazine decomposition was caused by CRES-304L, whereas CRES-347 caused the worst. CRES-303 was much more susceptible to iron leaching than CRES-347, and CRES-347 was more susceptible than CRES-304L. The JPL authors concluded that a  $\text{CO}_2$  content below 50 ppm would be acceptable for long-term contact with all three metals (less than 0.5% decomposition per year) [1638]. This compares to a MIL-SPEC limit of 30 ppm  $\text{CO}_2$  in high-purity-grade hydrazine as of 1999. Post-test examination of specimens under a scanning electron microscope revealed the formation of thin oxide films on aluminum, CRES, and titanium, which after drying tended to shrink and flake off the specimen surface when the film thickness exceeded 1 or 2  $\mu\text{m}$ . Short of applying a numerical rating scheme, the results were summarized by ranking the materials as acceptable or not acceptable with the qualifying terms “incomplete” or “restricted” attached. The term “incomplete” indicated in 1983 that not all the 10-year data were in. “Restricted” materials may be used for shorter

missions or in non-wetted parts of a system. In MIL-SPEC monopropellant-grade hydrazine, Al-2219-T86, Al-6061-T6, CRES-302, CRES-303, CRES-304, CRES-304L, CRES-316, CRES-321, and CRES-347 were considered acceptable, although the steels had a “restricted” qualifier. Stainless steels of types 350, 355, 416, 446, 17-4PH, and 17-7PH were rated acceptable despite pitting and surface discoloration. The best material identified after 10 years of testing was Ti-6Al-4V, although the data were incomplete.

The 10-year compatibility results milestone report was published in [1160, 1161]. It contained the results of the opening and examination of 36 ampoules containing hydrazine (8 of these containing the VIKING-grade hydrazine) and 8 with MMH. After 10 years, 164 specimens plus 28 hydrazine controls remained in storage. Another 59 ampoules contained samples in VIKING-grade hydrazine. Only 16 samples (Al, Ti, and controls) remained in the hydrazine/hydrazinium nitrate test, since all steel samples were found to be incompatible with this fuel and had to be terminated after only a few months of testing. Eight surviving samples and several controls were finally removed in 1984, and the results were presented in an interim publication [1648].

Interim results on 40 more hydrazine samples were reported in 1990 [1649]. These were the only long-term hydrazine samples opened between 1982 and 1989. As of 1990, the plan was to open the remaining several hundred samples that were approaching 20 years of storage at the rate of 50 samples per year. Unfortunately, funding limitations prevented a systematic completion of this well-planned test schedule. Several samples were taken out and temporarily put into a freezer, which would halt all further corrosion, awaiting their disposition and opening or disposal. Unfortunately, under the pressure of an environmental pollution cleanup campaign, all samples were hastily terminated in 1995 without gas pressure readings being taken and without analysis of the off-loaded hydrazine for leached metals and propellant deterioration. Owing to the shortsightedness of some government agencies, large amounts of valuable data were lost, which would take at least 20 years to obtain otherwise. This was a loss to the space propulsion community (government and industry) at large and a waste of taxpayer money. A hydrazine manufacturer had offered to analyze the off-loaded hydrazine samples for free, but the samples were hastily destroyed instead.

The JPL long-term storage test facility was also used in the 1980s for shorter (from half a year to 2 years’ duration) tests devoted to special objectives, such as tank components for a hydrazine actuation system [1162] or the effect of included air and carbon dioxide on the corrosion of stainless steel [1650]. Unfortunately, not all data obtained from the JPL program could be included here in this book because it would take up too much space. It would have been worthwhile to assemble all JPL data in spreadsheet format and post them on a web site so they could be readily accessed and searched by material type and propellant type. Valuable data might have been lost because they were never published.

**Material Compatibility Databases.** In the past, material compatibility data exchange between rocket propulsion engineers was mostly by way of conferences [1651,

1652], workshops, and information printed in hard copy [1634]. With the advent of personal computers and the Internet, the most efficient way to prevent future incompatibility problems with hydrazines and other rocket propellants would be by posting material compatibility test results and sharing them with other hydrazine users. Unfortunately, much of the material compatibility information rests in the archives of aerospace companies is considered proprietary information. Other material compatibility data were outright classified as confidential or “NOFORN, DoD use only” and could not be published here.

When it comes to priority in funding, material compatibility testing should be on an equal level of importance as toxicity testing in support of safety and hazard evaluation of propulsion systems, in particular for piloted missions. However, historically speaking, over the past five decades, a disparately large amount of funding has been devoted to toxicity testing and only a handful of thorough material compatibility studies has been published. Whatever little material compatibility information we have, it is scattered over many different publications. A few embarrassing material incompatibility incidents occurred in the aerospace community, but these are usually swept under the rug, as they say, and not widely published. Nobody has taken the time to assemble a so-called lessons-learned database to prevent the repetition of some of these expensive mistakes. What the spacecraft designer needs is a user-friendly database, either as a CD-ROM or as a periodically updated web site accessible to qualified users in the aerospace propulsion community. A plea was issued for the creation of a hydrazine material compatibility database [1653], but it has been left unanswered. What is needed is a material compatibility database that summarizes all material compatibility data of various metallic and non-metallic construction materials in contact with hydrazine propellants. In addition to the results of systematic material compatibility immersion tests, the database should contain a chapter on lessons learned from incidents caused by material incompatibility.

The extended-life capability of other spacecraft components (solar panels, traveling wave tubes) and future refueling capability generate an ongoing need for reliable long-term (longer-term) compatibility data. Problems caused by hidden material incompatibilities can be mission-threatening and pose a potential hazard to ground test personnel and astronauts, much more so than accidental inhalation of propellant vapors or splashes of propellants on unprotected skin. A failed mission would be much more costly than a hospital stay of an injured propellant handler.

The NASA Materials and Processes Technical Information System II (MAPTIS-II) was put into operation in 2003 (<https://maptis.nasa.gov>; accessed 9-Mar-2022). MAPTIS-II is a product of the NASA MSFC Engineering Directorate, Materials, Processes and Manufacturing Department, and Project Engineering Group. MAPTIS-II is a single-point source for physical, mechanical, and environmental properties for metallic and non-metallic materials for NASA and NASA-associated contractors and organizations and includes only limited corrosion data for propellants like hydrazine. Access is limited to users registered with US government agencies.

## 5.2 Methods of Compatibility Testing

The test methods described here for material compatibility testing with hydrazine can be equally well applied to other propellants, such as hydrogen peroxide or HAN-based monopropellants. Criteria used in selecting construction materials and determining material compatibility include pressure buildup in closed vessels by hydrazine decomposition, loss of structural strength of the material as a result of corrosion by hydrazine, and contamination of hydrazine by leached corrosion products. If a material that meets only one of these criteria is selected, the system may still fail because the other property requirements may not be met, which is sure to cause some unexpected problems. The test procedures used by many laboratories to determine compatibility differ significantly (as do the results). There is no standard ASTM or DIN method for determining compatibility of materials with hydrazine fuels. Many of the methods were adapted from other test methods for rocket propellants and corrosive materials. For the sake of being able to compare compatibility data from different sources on different materials and different propellants, it would be desirable if a standard compatibility test method could be agreed upon. This would be a task for one of the ASTM or AIAA standardization committees. It is widely recognized that different types of apparatus will be needed for ambient-, high-, and very high-temperature ( $>340\text{ K}$ ) testing, one for each temperature regime.

The various methods for material compatibility testing are summarized here for their applicability to hydrazine material compatibility, but the methods might be applicable to any other corrosive fluid as well. It is just that only a few corrosive liquids are so unforgiving when errors in material selection are made. Hydrazine is not only a corrosive, but also an energetic liquid. If anhydrous hydrazine is accidentally stored in containers made of materials of dubious compatibility, a catastrophe is sure to ensue.

Another question where no general agreement exists between material compatibility experts is whether the sample should be completely immersed in the liquid or only partially immersed, with part of it sticking out of the liquid and being exposed to the vapor phase. Total immersion is likely to give more reproducible results but may not be representative for real-life situations. There are many cases where observed corrosion was worst at the liquid-vapor interface. The cause may be that condensate refluxes from the vapor phase and washes contaminants and corrosion products down to the interface where they accumulate and accelerate the attack (in a stagnant system without forced convection). In other cases, the gas phase may contain trace oxygen or trace carbon dioxide, which makes corrosion by hydrazine worse at the interface, an effect that would be overlooked with total immersion. Table 65 gives a summary of partial/total immersion practices at different organizations. Some organizations conduct compatibility tests with partial immersion, while others specify total immersion.

**Table 65:** Hydrazine material compatibility – total vs. partial immersion

| Organization | Degree of immersion | References |
|--------------|---------------------|------------|
| SRI for JPL  | Two-thirds to total | [1647]     |
| JPL          | Half                | [1638]     |
| JPL          | Total               | [1161]     |
| PERME        | Total               | [1158]     |
| MIL-R-83412A | Total               |            |

### 5.2.1 Short-Term Exposure Tests

Before starting long-term material compatibility tests, a quick screening test will be useful to eliminate materials that are obviously incompatible. Such open-air, visual observation tests in a Petri dish will also need to be performed on materials that are not necessarily wetted with hydrazine by design but may be exposed to hydrazine in case of an accidental propellant spill during fueling or a leak. A procedure for casual exposure of materials to hypergolic fluids has been developed [1654]. A so-called casual exposure is assumed to last less than 240 min. Fabric and splash shield and goggle materials intended for use as personnel protective equipment will need to be subjected to more rigorous tests.

#### 5.2.1.1 Methods for Material Compatibility Evaluation

Methods for material compatibility evaluation include gas evolution measurements [1159, 1655–1658], differential pressure measurements [110, 241, 1158, 1659–1666], external strain gauges on sealed glass vials [1160–1162, 1638], Bourdon gauges [1647, 1667, 1668], microcalorimetry [1174, 1669], electrochemical impedance spectroscopy [1650, 1670–1677], dimensional and mass change measurements, sub-scale pressure vessels made from materials under test [1678–1680], and full-scale flight tanks made from materials under test. The last method is the most realistic, but it is also the most expensive method used in material compatibility testing for long-term missions. Only rarely is there enough time to conduct this type of test in real time prior to actual launch of a mission or fielding a weapons system. For some militarily strategic or tactical missile systems, it may be possible to go back in and do a post-storage disassembly and inspection (D&I) after the systems are decommissioned and demilitarized. Some tank storage tests are summarized in Section 6.8, where different tank designs are compared. The most expensive mode of tank storage testing is where the propellant is fed from the tank into rocket thrusters replicating a complete mission duty cycle on the ground. This may be part of a system development test, a system qualification test, or an after-the-fact troubleshooting exercise.

Gas evolution during hydrazine storage and material compatibility tests is often shown in graphical form of pressure rise plots. These graphs are of limited value or no value at all if the sample wetted surface area and the ullage volume of the apparatus

are not given. What can be learned from the shape of the curves alone is whether the sample passivates (slope is decreasing with time) or whether a protective coating is eaten away or leached contaminants result in progressive homogeneous decomposition throughout the liquid propellant sample (slope is increasing with time). Because pressure rise curves are hardly ever a linear straight line, one must average over an arbitrary time interval to determine gas evolution rates. Sometimes the first 60 d of a long-term test are ignored, and the rate is determined as if the experiment had only started on day 61. This is a better approximation of a linear slope for the prediction of pressures in the distant future.

Typical gas evolution data for two metals in hydrazine of three different purity grades at two different temperatures are summarized in Table 66. As can be seen, gas evolution on stainless steel is higher than on titanium, and removal of impurities reduces the gas evolution rate. This effect was more pronounced for the sample stored at room temperature.

**Table 66:** Gas evolution rate of metals in hydrazine.

| Metal     | Temperature, K   | Hydrazine purity grade | Years in test | Micromols of gas/cm <sup>2</sup> | Pressure rise factor, psia in. <sup>3</sup> in. <sup>-2</sup> year <sup>-1</sup> |
|-----------|------------------|------------------------|---------------|----------------------------------|----------------------------------------------------------------------------------|
| Ti-6Al-4V | 295              | Monopropellant         | 10.9          | 11.10                            | 0.14                                                                             |
| Ti-6Al-4V | 295              | Distilled              | 10.9          | 5.12                             | 0.06                                                                             |

<sup>a</sup> Sample spent only 1426 d at 313 K, stored at room temperature for remainder of test  
Data source: [1159]

Assuming that the gases in the low-pressure glass apparatus behave the same as in a pressurized flight tank and neglecting homogeneous decomposition, the pressure rise in tanks of given volume, wetted surface area, and ullage can be predicted from

$$P = \frac{KA t}{U}$$

where  $P$  is the pressure rise (psia),  $K$  is the pressure rise factor (psia in.<sup>3</sup> in.<sup>-2</sup> year<sup>-1</sup>; see Table 66),  $A$  is the surface area (in.<sup>2</sup>),  $U$  is the ullage (in.<sup>3</sup>), and  $t$  is the time (years). The pressure measured is the sum of the vapor pressure of hydrazine, dissolved ammonia, and permanent gases such as nitrogen and (formed to a much lesser extent) hydrogen.

Quite often the main reason for measuring the rate of gas evolution is to determine how much ullage must be left in the tank for a long-term space mission so as not to overpressurize the tank during the cruise and idle period. The concern for overpressure is caused by the permanent gases. At pressures approaching the proof and burst pressure of space flight tanks, all ammonia is in solution and it is only a minor contributor to the pressure in the vapor phase. In those cases where separate data on ammonia evolution and permanent gas evolution are available, only the permanent gases are used for pressure rise predictions.

The partial pressure of ammonia over hydrazine-ammonia solutions can be calculated from

$$P \cong \frac{N/m}{K}$$

where  $P$  is the partial pressure of ammonia (atm),  $N$  the mols of ammonia in the system,  $m$  the mols of hydrazine in the system, and  $K$  the equilibrium constant (0.0455 at 316 K) [1638]. If the test measures the effect of catalytic metal surfaces, the rate of gas evolution can be normalized by the wetted surface area of the metal coupon. If a galvanic couple is tested, the surface area by which the gas evolution is normalized is the sum of both coupons (although only one of them may be the culprit). If the vial does not contain a sample coupon and gas evolution occurs as a homogeneous hydrazine decomposition reaction (ignoring contribution from the glass), then the rate of gas evolution can be normalized by the volume of hydrazine in the test. The contribution of vapor-phase or homogeneous decomposition to the overall decomposition can be isolated by repeating identical tests with varying degrees of filling the test vessel. Tests conducted in a 32-L titanium tank filled to 12, 30, and 90% of its capacity with liquid hydrazine showed that the straight line did not intercept the origin of the axes at zero but had a positive intercept for the tank with zero percent liquid hydrazine [1158]. The surface of the vapor-phase titanium was never truly dry but was wet with condensate most of the time, and the surface-normalized rate of decomposition was independent of the degree of filling.

It is important that all hydrazine material compatibility tests be done with concurrent controls with vials that contain only hydrazine and no coupon. Sometimes the rate of gas evolution of the control is deducted from that of a test coupon before the gas evolution is normalized by the wetted surface area.

#### 5.2.1.2 Identification of Evolved Gases

Theoretically, the products of hydrazine decomposition that are responsible for unwanted pressure buildup during storage are nitrogen, ammonia, and hydrogen. Under the conditions of slow decomposition in the liquid phase (Section 4.4), mainly nitrogen and ammonia and only a trace of hydrogen are formed. At room temperature and sea-level pressures, most of the ammonia will stay in solution in the hydrazine and not contribute to the pressure in the ullage. One would have to evacuate the sample

and pump off the ammonia to obtain a complete ammonia analysis. Gas evolution rates reported by different authors often differ because the ammonia partial pressure is included or omitted, depending on the operating conditions of the test. Tests that start out at vacuum will include the ammonia in the gas evolution calculation. Other tests that start out at 1 bar and increase in pressure from there will leave most of the ammonia dissolved in the liquid. The composition of the evolved gas after terminating long-term compatibility tests has been analyzed by several investigators, but such an analysis is not routinely performed.

In one series of 51 material compatibility tests with hydrazine, the mol ratio of nitrogen to hydrogen in the non-condensable portion of the gas phase was analyzed by mass spectrometry and ranged from 12 to 57 [1647]. In a similar test with 76%  $\text{N}_2\text{H}_4$ /24%  $\text{N}_2\text{H}_5\text{NO}_3$ , the ratio ranged from 5 to 28. Mixtures of hydrazine or water with hydrazinium nitrate may also evolve hydrogen azide.

Sometimes one can make an approximate statement about the likely composition of the gas evolved at the end of the experiment by cooling the sample in increments to 273, 240, and 80 K (fractional condensation, gradually condensing ammonia, then nitrogen) and measuring the pressure at each temperature.

Only 1% by volume hydrogen was found in the vapor space of hydrazine material compatibility tests using different test setups [1158]. As shown in Appendix A of that paper, the pressure increase measured in samples starting at atmospheric pressure can be corrected for the dissolved ammonia.

### 5.3 Compatibility of Hydrazine with Structural Metals

As already mentioned, it has become difficult to quickly qualify materials for use with hydrazine during long-term deep-space missions lasting up to 10 or 20 years. Besides accelerating corrosion rates by superimposed electric potentials as described in one of the preceding sections, one can also extrapolate from short-term data obtained by radioisotope tracer methods [1681–1685]. So far, both methods have been applied to metals only. Using radioactive Type 304 corrosion-resistant steel and liquid hydrazine yielded data about the metal uptake by hydrazine that heretofore had never been generated. The data showed a continual increase in the concentrations of iron and chromium as a function of time over a period of 7 months. The concentrations of these metals as a function of surface area at constant time were not as expected, however.

A summary of literature references dealing with metal compatibility tests with hydrazine, arranged by type of metal and type of test, is available in [1686]. It is very difficult to condense this much information into a single table. Individual metals are discussed in subsequent paragraphs in alphabetical order, not necessarily in the sequence of preference for tankage or valve materials. Many of the reports referenced here deal with more than one propellant in addition to hydrazine. Sometimes the same

report contains valuable information on methylhydrazines, which constitute less of a metallic material compatibility problem than hydrazine itself.

Incompatibility of metals with hydrazine can be caused by either catalytic decomposition of hydrazine on the metal surface or by chemical reaction of hydrazine with the metal. Chemical reactions will leave the metal pockmarked with corrosion pits, oxide films may form on the surface and subsequently flake off, and leached metals will contaminate the hydrazine.

Besides the planned duration of a mission, the wetted surface area also determines whether or not a metal will be acceptable. The rate of gas evolution in hydrazine is generally proportional to the wetted surface area, indicating a mechanism of heterogeneous catalysis as opposed to homogeneous catalysis (often the result of dissolved contaminants), in which case the gas evolution would be proportional to the volume of liquid in the tank. If a component that has to be made of a metal of marginal compatibility is only exposing a small surface area, such as in the ram of a pyro valve or the valve seat of a hard seat valve, the material may be acceptable in spite of a high rate of gas evolution when immersed in hydrazine at elevated temperatures. If the wetted surface area is as large as the tank wall surface or even the wire mesh in a surface tension propellant management device (PMD) or a micron-rated filter, then extreme demands are made for low rates of gas evolution. One and the same metal may be acceptable in one location but not in another.

Low rates of gas formation are important in designing a hydrazine system. Besides concern about overpressurizing the tank or slugs of liquid trapped between two valves, there is also concern about bubbles trapped in the propellant line, which may be hot spots when compressed adiabatically. Thrusters firing in pairs might throw the spacecraft into a wild spin if only one of the two ingests a bubble and the other does not. Bubbles passing through the gas generator of hydrazine arcjets may cause the arc to extinguish. For these reasons, the rate of gas evolution must be kept at a minimum by selecting only materials that are fully compatible with hydrazine.

Quite often data may be available for one of the three propellant hydrazines, but not for the hydrazine of interest. To a limited extent, it is possible to extrapolate metal compatibility data from one hydrazine to another. For metallic materials, the extrapolation is easier than for non-metals. Metals found to be compatible with hydrazine will most likely also be compatible with MMH and UDMH. Similarly, metals found to be compatible with MMH will most likely also be compatible with UDMH. Polymeric materials are more likely to swell in UDMH than in MMH or hydrazine.

### 5.3.1 Compatibility of Aluminum Alloys with Hydrazine

Aluminum will frequently be preferred for the design of spacecraft and service with hydrazine because it is economical to obtain and easy to machine. Unfortunately, several aluminum alloys are incompatible with anhydrous hydrazine, and *none* of the aluminum alloys can be used with hydrazine hydrate. The addition of water to alu-

minum samples in hydrazine or the use of impure hydrazine results in rapid loss of the protective oxide layer, and gassing ensues [1687]. When water was accidentally allowed to enter drums with aluminized drums, the drums exploded. Threads on aluminum drum closure plugs that are wetted by hydrazine on one side and exposed to ambient atmospheric moisture on the other side will gradually corrode. There was a short period in the last century when hydrazine was shipped in aluminum drums, but this practice was soon discontinued.

Aluminum bomblets made from Al-1100 and Al-6061-T6 had to be prematurely removed from a material compatibility test with MIL-SPEC hydrazine at 408 K (275 °F) [1678, 1679]. The pressure in the Al-1100 bomblet exceeded 1.4 MPa (200 psig) in less than 64 h, and the gas evolution rate was  $4 \times 10^{-6} \text{ cm}^3 \text{ s}^{-1} \text{ cm}^{-2}$ . The Al-6061-T6 bomblet fared only slightly better and had to be removed after two 64-h heating cycles. The gas evolution rate of aluminum in contact with hydrazine is an order of magnitude higher than that of titanium. All aluminum alloys showed evidence of corrosion. Hydrazine off-loaded from the bomblet was visibly contaminated by a white gelatinous precipitate. Despite obvious signs of corrosion, the tensile strength of the two aluminum alloys was not affected after the relatively short duration of the test.

Aluminum cylinders containing 3.5–5.5 L of MIL-SPEC standard-grade hydrazine and made of Al-2014-T6 or Al-6061-T6 were used during a 2-month storage test [1688]. Different cleaning procedures (chem-milled, liquid-honed) did not affect the rate of pressure buildup. A slow pressure increase was noticeable only during the first half of the test. Although the appearance of the inside of the tanks had changed where it was exposed to liquid hydrazine, the relatively short tests revealed no gross incompatibility. Based on results from a 10-year compatibility test, aluminum alloys Al-6061-T6 and Al-2014-T6 were rated as acceptable but were restricted because of moderate corrosion and the formation of a surface film that flaked off. The film did not appear to catalyze propellant decomposition. If it flakes off, it may plug filters and valves. Following the small-scale tests, a flight-weight 1.48-m<sup>3</sup> (55-cu.ft.) aluminum tank made from Al-2014 was filled with 1169 kg (2580 lb) hydrazine and stored in a desert climate for 3.5 years. Several hydrazine samples were taken and analyzed during the storage tests. At the end of the storage test, the off-loaded hydrazine was test fired in an uncooled bipropellant rocket engine with NTO as the oxidizer.

The following aluminum alloys were rated acceptable for brief general service based on 7- to 90-d immersion tests [1636]: 2S, 2SO, 2SH, 3S, 3SH, 24ST, 52ST, 61ST, and 75ST. Other aluminum alloys can be used only for limited service: 40E, 43, and 716. The same rating was given for hydrazine hydrate service, which is somewhat surprising and very doubtful because most aluminum alloys react with all alkaline solutions, including hydrazine hydrate solutions. Aluminum alloys that contain zinc are most certainly not recommended in contact with hydrazine.

It is interesting to note that for a short period in the 1960s, Rocky Mountain Arsenal shipped anhydrous hydrazine in aluminum drums. It is not known why the use of aluminum drums for the transport and storage of hydrazine was discontinued. One

source commented that closure plug diameters of the aluminum drums were different from those in CRES drums. This difference required propellant transfer personnel to keep two sets of eductor tools, one for CRES drums and one for aluminum drums, which made it more difficult and made the aluminum drums less popular. Anhydrous hydrazine offered by the People's Republic of China in the late 1980s was to be shipped in aluminum drums holding 100 kg hydrazine.

As part of a composite overwrapped aluminum-lined propellant tank with aluminum PMD development effort, long-term compatibility and wettability testing with hydrazine was performed on Al-6061 and Al-2219 coupons fabricated and cleaned by conventional processes [1689, 1690]. Long-term compatibility was confirmed. However, the wettability of the conventionally cleaned aluminum as measured by contact angle produced higher than desired angles ( $> 30^\circ$ ) with excessive scatter. A cleaning or treatment process was developed to produce consistently low contact angles, i.e., good wettability.

### 5.3.2 Compatibility of Stainless Steels with Hydrazine

Stainless steels are usually subdivided into martensitic (e.g., CRES-440), ferritic (e.g., CRES-430F), and austenitic (e.g., CRES-304) steels. Sometimes the same numbers are carried with an AISI designation. The austenitic group is non-magnetic; the martensitic and ferritic groups (CRES-400 and 4000 series) are magnetic and therefore often used for armatures in solenoid valves, where they are also wetted by hydrazine. The 300-series stainless steels show in general good compatibility with hydrazine but often lack the strength for lightweight, flight-weight, thin-walled tanks that need to be pressurized. Precipitation-hardened age-hardenable (PH) steels have the strength and hardness required for many container applications but are not very compatible with hydrazine, mainly due to their molybdenum content. Despite this disadvantage, small components with only small wetted surface areas in valves have been made from PH steels. When in contact with air and moist hydrazine, these steels often rust and that makes things even worse.

Materials used in the construction of hydrazine hydrate manufacturing plants are mainly stainless steel. The first large plant constructed in the 1940s in Gersthofen, Germany, used V2A steel in most of the distillation columns. V4A steel was used in the salt separator and the lower portion of the concentrating distillation column.

In compatibility tests with bomblets manufactured from CRES-321 simulating a spacecraft sterilization process by six heating cycles to 408 K (275 °F) for 64 h each, the CRES-321 bomblet had to be removed after only three heating cycles because the pressure exceeded 1.37 MPa (200 psig) [1678, 1679]. The pressure rise data from the test indicated that 3% ullage volume at 408 K (275 °F) was enough to prevent excessive pressure buildup if titanium tanks are used. The gas evolution rates of CRES-321 were more than four times higher than those of Ti-6Al-4V, namely,  $2.1 \times 10^{-6}$  compared to  $3.5 \times 10^{-7} \text{ cm}^3 \text{ s}^{-1} \text{ cm}^{-2}$ .

Based on the results of 10-year storage tests at 316 K (110 °F), CRES-302 and CRES-303 caused excessive pressure buildup. CRES-304L, CRES-308, and A-286 were thoroughly tested as tank materials for a long-term storage missile application [1159, 1691, 1692].

In high-temperature storage tests, three explosions were encountered with hydrazine in CRES-347 and PH15-7Mo stainless-steel tanks above 416 K (290 °F) [1693]. After 16 h of continued heating at 416 K (290 °F), an explosion occurred with  $N_2H_4$  in a CRES-347 stainless-steel tank, demolishing the oven and part of the building. Prior to this event, the pressure rise rate had been 179 kPa/h (26 psig/h). Subsequent investigation pointed to decomposition of  $N_2H_4$  in stainless-steel tank No. 2, which shattered, sending shrapnel at the other seven tanks, causing tank Nos. 1 and 4, which also contained hydrazine, to rupture. Other than slight decomposition, no such problems were encountered with UDMH in identical tanks at temperatures up to 422 K (300 °F). This would indicate that hydrazine is more reactive and less forgiving than UDMH.

CRES-303 was found to exhibit a high rate of gas evolution and iron leaching after 12 years in hydrazine at 316 K [1649]. In the same test series, CRES 17-7PH had a very high rate of gas evolution, and a welded bimetallic CRES-301/CRES-304 sample with a high rate of gas evolution was suspicious due to possible contaminants in the weld bead.

The rate of corrosion of CRES-304 and all other steels increases dramatically if hydrazine becomes contaminated by absorbed carbon dioxide. As long as the carbon dioxide pickup is carefully controlled (i.e., minimized), anhydrous hydrazine can be stored in CRES tanks in tactical or strategic rocket propulsion applications for more than 10 years (Section 6.8).

Cast iron, whether gray cast or ductile or nodular, and all AISI 1000-series carbon steels cannot be used for anhydrous hydrazine or hydrazine solutions.

CRES-304 does not normally contain molybdenum. CFR49 § 173.276(a) (4) and (6) prohibits the transportation of hydrazine in a tank car made of steel that contains more than 0.5% Mo. The rationale for this restriction is not well documented. Although alloys like AM350 (3.25% Mo, 5% Ni, 17% Cr) and AM355 (3.25% Mo, 5% Ni, 16% Cr) would never be used to make tank cars, they have been used for components in hydrazine systems. CRES-316 with 3% Mo is widely used for valve components and has been used in ground support equipment (fuel carts, 4BW cylinders) without any undue effects. CRES-A286 has 1.25% Mo and is considered compatible with hydrazine [1162]. The adverse effect of molybdenum on hydrazine compatibility of steels may have been overestimated. Lawton, Moran and DiStefano [1650] stated that “*The presence of molybdenum in stainless steels to the 3% level is not necessarily deleterious, contrary to published reports,*” and continues, “*Alloys containing up to 3% Mo can be compatible with hydrazine for at least 13 years.*” Of course, it depends on which component of a propellant feed system is under consideration and how much surface area is wetted.

### 5.3.3 Compatibility of Titanium Alloys with Hydrazine

Titanium alloys combine good strength:weight ratios with nearly infinite duration compatibility with hydrazine, making them the preferred material for all long-term mission hydrazine tanks. Examination of titanium tanks after numerous extended storage tests with hydrazine has not revealed any signs of corrosive attack [1694–1697].

Chemically pure titanium may show good material compatibility but lacks the strength of alloys like Ti-6Al-4V. Different grades of so-called chemically pure titanium differ by the amount of iron allowed (which has a pronounced effect on hydrazine compatibility). Chemically pure titanium may be used in locations where maximum strength is not required or where malleability is desired, as in crimped joints of PMDs or in crushable seals.

One of the very early material compatibility reports erred in its conclusion that Ti-6Al-4V was not compatible with hydrazine [1647]. It is not known what caused a Ti-6Al-4V sample coated with Apiezon-L to behave poorly. The early SRI program may have had unrecognized amounts of residual halogenated cleaning solvents included in the sealed ampoules.

Unaged welds in Ti-6Al-4V of normal interstitial content are extremely susceptible to sustained-load crack growth (SLCG), in particular in the presence of chloride contamination [1698–1700]. Aging both the weld itself and the heat-affected zone for 4 h at 783 K reduces susceptibility to SLCG. Fracture mechanics design curves of crack growth threshold stress intensity vs. temperature are generated from 313 to 344 K (40 to 71 °C).

Titanium-6Al-4V is not sufficiently ductile to be drawn. The machining of tank hemispheres to final shape is a very costly operation. As opposed to Ti-6Al-4V,  $\beta$ -titanium has excellent formability, and conventional hydroform equipment can be used to make deep-drawn tank shells to near net shape. A more ductile alloy, Ti-15V-3Cr-3Al-3Sn, became available in the 1970s and now offers a significant cost and weight reduction in flight-weight titanium tanks for hydrazine or MMH because it can be drawn [1701–1703].

A large amount of information exists on the attack of methanol on titanium under various conditions that may cause hydrogen embrittlement. Care must be taken in selecting cleaning agents for titanium to make sure that they do not contain methanol. Hydrazine is not likely to contain methanol as a contaminant, and hydrazine/methanol blends have rarely been used as propellants. See also [1704].

### 5.3.4 Bimetallic Specimen Corrosion in Hydrazine

The potential problems of galvanic corrosion in a good electrolyte such as hydrazine have frequently been overlooked. The JPL studies are particularly valuable because they included many bimetallic specimens either in isolated juxtaposition or in electrical contact with each other [1161, 1638, 1705]. Several of the bimetallic contact speci-

mens had to be pulled from the test chamber early because of excessive pressure rise, indicating the importance of this corrosion mechanism.

Weld beads of CRES-308 filler on CRES-301 tanks had a higher rate of gas evolution than the metals by themselves [1659, 1660]. Joints between titanium and stainless steel showed relatively high rates of pressure buildup [241]. The pressure buildup rates were higher by a factor of 20 than those of the metals by themselves. The use of bimetallic joints in propulsion systems performing long-duration missions was judged undesirable. Despite this controversy, the VOYAGER (MJS 77) propulsion systems did include transition tubes from the Ti-6Al-4V tank to CRES-304 tubing, apparently without ill effects on system performance. Such transition joints are now in routine use on many other spacecraft.

Aluminum Voi-Shan or similar soft seals are not suitable for sealing stainless-steel fittings for hydrazine service. Disassembly of threaded fittings revealed severe corrosion of aluminum seals in contact with stainless steel [1635]. Some of the damage may have occurred after most of the hydrazine was flushed out with water and the fittings were wet with alkaline water. Aluminum and stainless steel in hydrazine or Aerozine-50 form a galvanic element with accelerated corrosion [1706].

### 5.3.5 Metals Leaching into Hydrazine

Data on metals leached from 304 stainless steel into 15 mL MIL-SPEC propellant (standard) grade hydrazine at a surface : volume ratio of  $0.394 \text{ cm}^{-1}$  and (presumably) ambient temperature showed a linear relationship on a double-log graph (metal concentration vs. time). The amount of iron and chromium leached from a specimen of CRES-304 was determined by a radioactive tracer technique. The metal ion concentration increased from 0.05 ppm after 1 d to 30–60 ppm after 120 d [1635]. In the presence of carbazic acid in hydrazine, this rate can be many times higher [1638].

### 5.3.6 Stress Corrosion of Metals in Hydrazine

Most metal compatibility tests with hydrazines so far have been conducted with unstressed coupons under static conditions in stagnant fluids. Stress corrosion was not observed in pure hydrazine, and a few stress-corrosion-type failures that did occur have been blamed on contaminants. Stress corrosion cracking (SCC) is an insidious phenomenon difficult to detect in its incipient state. It is often caused in an innocuous environment by stresses derived from applied loads. Residual stresses from heat treatment, forming, extruding, rolling, and welding may aggravate the situation. Cracks in titanium alloys can propagate either between or across grain boundaries.

A more detailed investigation has shown that some metals are indeed susceptible to stress-corrosion crack growth in liquid hydrazines. Stainless steel 410, used as a tankage material in the DELTA 89 vehicle, showed stress-corrosion susceptibility with Aerozine-50 that was most likely contaminated with carbazic acid by the absorp-

tion of atmospheric carbon dioxide. In tests with the alloy AISI 4130, a high-strength, low-alloy material that was selected as a test material because it is known to be highly susceptible to stress corrosion in several fluids, hydrazine was the more active fluid causing stress corrosion [1707]. Although AISI 4130 is generally not recommended for anhydrous hydrazine service because it rusts too easily, it is compatible with MMH and UDMH, based on static compatibility test results. In addition to 4130, for which stress corrosion in contaminated hydrazines was not unexpected, several other alloys, stainless steel 410, titanium-6Al-4V, aluminum-6061-T6, and Inconel 718, were also tested for stress-corrosion susceptibility. These alloys find more frequent use in components where they are wetted by hydrazine. The metal specimens were pre-cracked by fatiguing, and then a tapered plug was inserted to load the stressed area. The plug was not immersed in the liquid. The liquid level reached only to and above the pre-cracked area. With AISI 4130 no crack extension occurred in UDMH up to at least 2000 h, whereas MMH caused growth after 500 h and hydrazine, after about 60 h. Hydrazine was more active in causing stress corrosion than was MMH or UDMH. Methylhydrazine, in turn, was more active than UDMH. The aforementioned alloys can be ranked in the following order of decreasing susceptibility to stress corrosion: 4130 steel, CRES-410, Inconel 718, Ti-6Al-4V, and Al-6061-T6. Steel AISI 4130 failed after 60 and 20 h when propellant-grade hydrazine was spiked with 0.2 and 1% CO<sub>2</sub>, respectively, whereas it sustained the maximum stress intensity without failure for the entire duration of the 4000-h test if the hydrazine was pre-treated with barium oxide to remove carbazic acid. Similarly, water addition (5 or 30%) shortened the time to beginning failure from 50 to 40 and 10 h, respectively. The action of carbazic acid on stress propagation is very rapid. If a stressed sample is kept in BaO purified hydrazine where no crack propagation can be observed and the purified hydrazine is replaced with untreated hydrazine, crack growth will commence within a short period. No crack growth was observed with Ti-6Al-4V, but other investigators using different sample geometries have observed SCC of this material in Aerozine-50 [1708, 1709].

SLCG studies are closely related to SCC. In studies with Ti-6Al-4V coupons in hydrazine, using uniaxially loaded fracture mechanics specimens containing part-through cracks, an electric-discharge-machined notch was used to start the crack [1698–1700]. Pre-cracking before sustained-load testing was done by cyclically loading the notch in bending. Then three specimens were loaded in tandem in a standard creep testing machine. The applied stress intensity during sustained loading was varied by changing the width of the three simultaneously loaded specimens. The hydrazine was pressure-forced into the crack, and the samples were stressed and exposed for 24 h at 333, 339, and 344 K (140, 150, and 160 °F). Following hydrazine exposure, the samples were cleaned, dried, and marked, and the fracture was completed in air. The appearance of a crack formed in air was different from that of a crack formed while wet with hydrazine. The fracture surface was studied under a scanning electron microscope to identify the contribution of hydrazine exposure to crack growth. In this test, unaged weld metal in Ti-6Al-4V of

normal interstitial content was very susceptible to SLCG. One specimen was tested in helium, and only very little crack growth occurred. SLCG in a similar unaged weld sample in hydrazine under otherwise identical conditions occurred under much lower loads, showing that SLCG was actually caused by the hydrazine. Aging of both metal and heat-affected zone at 783 K for 4 h after welding removed this susceptibility completely. Unaged weld metal and heat-affected zones were less susceptible to crack growth in VIKING-grade hydrazine than in MIL-SPEC hydrazine, indicating a possible contribution by the trace contaminants usually found in commercial anhydrous hydrazine prior to 2004.

As a continuation of these studies, the same technique was used to study the effect of cleaning fluids, residual cleaning fluids, and chloride contamination in hydrazine on SLCG in Ti-6Al-4V [1699]. In this study, a forged titanium tank was cut into slabs, solution-treated at 1227 K for 1 h, water quenched, and then aged at 783 K for 4 h. Panels of aged forging material were welded together. Some of the welded specimens were aged in argon at 783 K for 4 h, but most of them were tested in the “as-welded” condition because actual flight tanks cannot be subjected to aging treatment without distortion. Monopropellant-grade hydrazine per MIL-26536C Amendment 1 was used for these tests. In one series, the hydrazine was deliberately contaminated with 90 ppm hydrogen chloride. The effect of chloride on SLCG is believed to be limited to Ti-6Al-4V sheet. Ti-6Al-4V was more susceptible to SLCG in isopropyl alcohol than in any of the hydrazine propellants. In addition to concern about SLCG in liquid hydrazines, there is also concern over SLCG in hydrazine decomposition products, such as moist ammonia.

#### **5.3.6.1 Effects of Acidic Contaminants**

Acidic impurities derived from nitric acid, carbon dioxide, or halogenated solvents in hydrazine and hydrazine fuels are said to cause material failure by hydrogen embrittlement. For instance, welds in type 410 steel failed in 3–10 d under load when exposed to contaminated Aerozine-50 but did not fail even after 30 d in much more corrosive nitrogen tetroxide. The addition of potassium hydroxide to hydrazine and hydrazine fuels is claimed to neutralize acidic contaminants and prevent hydrogen embrittlement [1698–1700].

#### **5.3.6.2 Effects of Carbon Dioxide/Carbazic Acid**

During a study of the kinetics of CRES-304L corrosion by hydrazine, it became apparent that the amount of carbazate/carbazic acid in the system has a pronounced effect on the rate of corrosion [1682–1685]. The CRES-304L coupons used for the tests were cut from the same manufacturing lot number as those used in JPL’s long-term storage test to allow some correlation between the two methods. First, CRES-304L coupons were immersed in a static test into hydrazine at 316.5 or 344.5 K with varying amounts of carbon dioxide added. The hydrazine contained less than 3 ppm CO<sub>2</sub> to start with and was doped with 13, 50, and 86 ppm CO<sub>2</sub> during the test. The hydrazine contained

1318 ppb Fe, 65 ppb Cr, 4 ppb Mn, and 161 ppb Ni at the beginning of the test. The increase in iron as measured by atomic absorption spectroscopy (AAS) was the most sensitive indicator of ongoing steel corrosion. For the first 30 d, the rate of iron buildup was roughly linear and independent of the amount of CO<sub>2</sub> added. After 30 d the rate of corrosion suddenly increased. The acceleration was proportional to the CO<sub>2</sub> content. It appears that during the first 30 d the steel was partially protected by an oxide layer. Once the passivation layer was removed, corrosion chemistry could act directly on the fresh metal surface. The leached metal content increase eventually leveled off after 160 d because the carbazic acid was depleted. It appeared that the CO<sub>2</sub> was not regenerated in this process. In some instances, at the highest CO<sub>2</sub> levels tested, leached iron concentrations approached 25 ppm and precipitates of iron carbazates formed in the hydrazine. Such precipitates would be devastating in a flight system where they might clog filters, valves, and capillary injector tubes and cause flow blockage of hydrazine propellant to the thrusters.

It would be desirable to develop a rate expression that provides the hydrazine user with a predictive tool with which the rate of pressure rise and metals leaching can be predicted as a function of CO<sub>2</sub> content, temperature, pre-treatment of the metal surface, ullage fraction, and surface: volume ratio. Due to the many variables involved, no such generally valid equation exists at this time. A first attempt resulted in a two-part rate expression, one for the first 30 d and one for days 31 through 160 [1684].

In an effort to minimize pressure buildup in CRES-304L tanks for a post-boost control system application, the effect of CO<sub>2</sub> contamination on pressure rise rate was subjected to a very thorough examination [1692]. A group of propellant storage assemblies (PSAs) was loaded with hydrazine doped with known amounts of CO<sub>2</sub> in a range of 30 to 200 ppm CO<sub>2</sub>. A good correlation between the pressure rise rate and the CO<sub>2</sub> concentration was demonstrated. The MIL-SPEC limit of 50 ppm CO<sub>2</sub> was deemed too high to achieve 10-year storability in CRES-304L.

Hydrazine decomposition in a 1.348-L CRES-304L stainless-steel tank with 11% ullage was strongly affected by the amount of carbon dioxide (carbazic acid) contained in or added to the hydrazine [1178, 1179]. Addition of up to 229 ppm CO<sub>2</sub> increased the gas evolution rate from 0.6 to 15.9 cm<sup>3</sup> STP/d at 333 K (60 °C). Five different CO<sub>2</sub> concentrations were tested, and the rate of gas evolution increased linearly with the amount of CO<sub>2</sub> added, but at least 20 ppm were required to obtain a noticeable effect. The amount of iron leached from the tank wall also increased from 1 to 18 ppm in the off-loaded hydrazine. The concentration of nickel or chromium leached at the same time increased also but reached only 2 ppm at the most. A distinction was made between labile and non-labile carbon dioxide, where the non-labile is complexed in metal carbazate salts and is no longer corrosive. It is important to re-emphasize that it is not the carbazate ion or its complexes that make hydrazine more corrosive toward metals, but the hydrazinium ion. The carbazate ion only provides a mechanism for instant removal of free metal ions by complexation, which is a driving force for additional metal removal and conversion to metal ions. This is explained by the law of

mass action as an equilibrium that is constantly shifted in one direction by the removal of one reactant (free metal ions).

In the early 1970s it was stated that “*Unless further specific data is available, it should be concluded that material compatibility ratings are not improved by using purified hydrazine*” [1635]. Surprising as this may be, this is probably still true, since materials that are not compatible with mono-grade hydrazine will most likely not be compatible with high-purity hydrazine either. This raises the question as to why one goes through the expense of using high-purity hydrazine for material compatibility testing when some answers can be obtained more economically with mono-grade hydrazine. The relative ranking of candidate metals remains the same, but if one wants to predict the pressure rise after 10 or 20 years in space, then the test will have to be done with high-purity hydrazine, and no lower-grade substitutes can be accepted.

During a thorough examination of the effect of doping hydrazine with 190 ppm CO<sub>2</sub> on the corrosion of Ti-6Al-4V in two heat treatment states, AM-350 and AM-355, at two different temperatures, 316 and 333 K, samples were withdrawn after 139, 182, 293, and 328 d of testing [1650]. Within experimental error, the two microcrystalline forms of Ti-6Al-4V behaved the same at both temperatures and regardless of whether or not the hydrazine was doped with CO<sub>2</sub>. The addition of CO<sub>2</sub> accelerated the decomposition of the hydrazine, but it did the same in the blanks, which did not contain any metal coupons. With AM-350 and AM-355, there was a pronounced effect of heat treatment on hydrazine compatibility as measured by gas evolution. AM-355 was subjected to the heat and chill treatment recommended by Carpenter Technology Corp. for maximum resistance to halide corrosion. In the case of hydrazine, the heat treatment made the AM-355 metal more susceptible than the as-received, untreated alloy. Either of the two AM alloys caused significantly more hydrazine decomposition and iron leaching if the hydrazine was doped with 190 ppm CO<sub>2</sub>. SEM examination of the metal surface after the test revealed pronounced attack at the grain boundaries. SEM-EDAX spot images showed possible depletion of Mo, Si, and O at the grain boundaries and pits.

In the search for clogging materials causing flow decay, the flow properties of hydrazine doped with CO<sub>2</sub>, ammonia, or water were measured by flowing hydrazine through a 0.127-mm (0.005-in.) capillary test section using an extrusion rheometer [1710]. The extrusion rheometer used during a previous program was modified to improve heat transfer characteristics. Although flow blockage occurred in two runs and flow decay occurred in another two runs, the cause was not identified, and no gelatinous material was observed.

### 5.3.6.3 Effects of Halogen-Containing Contaminants

In many cases it is not the chloride or fluoride ion as such, but the acidity accompanying it in the form of N<sub>2</sub>H<sub>5</sub>Cl or N<sub>2</sub>H<sub>5</sub>F that can cause severe corrosion of hydrazine systems. The results will differ if chloride is added as NaCl or N<sub>2</sub>H<sub>5</sub>Cl. Hydrazine that has become contaminated by Freon-TF (a cleaning solvent) or Freon-13B1 (used as a pressurant) will attack stainless steels and braze alloys [1711]. Freon-13B1 was

at one time used as a pressurant fluid to expel hydrazine from a positive expulsion tank with a stainless-steel diaphragm, but the metal diaphragm may have leaked, resulting in hydrazine contamination. In another case, Freon-13B1 was considered as a pressurant for hydrazine in an AF-E-332 bladder tank, but the Freon had high permeability through the elastomer and would have saturated the propellant with Freon. The effects of Freon-13B1 on catalyst survival were not tested. It is assumed that the halogenide contamination would have been disastrous on the catalyst activity and durability. Freon-TF is a more deleterious contaminant than Freon-13B1. Freon-TF, even in trace amounts of contamination in hydrazine, increased the rate of gas evolution from hydrazine in contact with CRES-304L at 298 K by a factor of six. Contamination by 0.033 mass-% Freon-13B1 increased the rate of gas evolution of CRES-304L at 298 K by a factor of eight based on 100 h of exposure and by a factor of 5.5 based on 500 h of exposure. The corresponding factors for CRES-308 were 55 and 25.6, and for the bimetallic braze joint they were 734 and 199. Both CRES-304 and Au-Ni braze resisted the Freon-contaminated hydrazine better than did CRES-308 and Cu braze.

Chloride and fluoride resulting from residual CFC-113 (Freon-TF from a cleaning process) that was accidentally not removed when the ampoules were loaded with hydrazine accelerated the corrosion of many metal specimens tested at JPL [1160, 1638, 1649] and rendered some of the test results useless or dubious. It is possible to study the effect of halides on metals corrosion in hydrazine by sorting the results by halide concentration and plotting the halide concentration against parameters of corrosion (metals leaching, gas evolution, hydrazine decomposition).

The effect chloride ion at up to 100 ppm has on SCC tests of Al-2014-T6, CRES-304L, and Ti-6Al-4V in UDMH will be discussed in the chapter "Dimethylhydrazines." Many titanium alloys in other fluids are sensitive to chloride contaminations on the order of 1 ppm.

### 5.3.7 Compatibility of Metals with Hydrazine Solutions

It may be difficult enough to find structural metals that are compatible with hydrazine and hydrazine mixtures, but the problem becomes much more difficult if one must find materials for hydrazine solutions, such as hydrazinium nitrate (HN) in hydrazine.

**Binary Blends.** Based on the Brønsted acid theory, a solution of HN in hydrazine is tantamount to a solution of nitric acid in water, and the corrosion problems are accordingly aggravating. Early compatibility tests with three hydrazine/HN/water mixtures (and hydrazine as a baseline) showed very rapidly that wrought iron, cast iron, Armco iron, brass, copper, monel, cobalt, molybdenum, manganese, stainless steel 18-8, lead, zinc, nickel, and magnesium are not suitable for HN service [242]. Aluminum and titanium showed no apparent reaction.

For a 24% HN/1% H<sub>2</sub>O/75% N<sub>2</sub>H<sub>4</sub> propellant, stainless steels are not acceptable because of rapid corrosion and gas evolution. Some of the glass sample ampoules con-

<sup>a</sup> Data source: [1648]

taining stainless steels ruptured during the first few months of the test, whereas other ampoules with titanium and aluminum alloys remained in test for up to 14.5 years at 316 K [1648]. Aluminum-6061-T6 is considered only marginally acceptable. Even if the pressure rise with aluminum alloys can be tolerated, the formation of aluminum oxide flakes and sludge may clog surface tension screens and filters or cause valves to leak **internally** if it prevents complete closure of the valve. Titanium-6Al-4V was rated provisionally acceptable [1160, 1638] but is still the best choice of all other candidate metals [1648]. This test series is very valuable because it systematically examined galvanic couples of dissimilar metals. Gas evolution rates measured on a few samples are summarized in Table 67 in comparison to those observed with hydrazine by itself.

For many published samples the final pressure in the ampoules is not available because they may have ruptured before a final measurement could be taken. In these cases, the short duration of the test, often less than 100 d, was an indication of incompatibility. In other cases, a pronounced weight loss (up to 9%) of the sample caused by corrosion and metal leaching is proof of incompatibility. The data in Table 67 above were extracted from a spreadsheet of 71 samples with HPB-2400 or HPB-2401. There are two columns of gas evolution rates normalized by the wetted surface area: The first

was calculated from the pressure reading and the known ullage volume, the second is based on actual measurement of nitrogen and hydrogen gas volume collected in a vacuum system when opening the ampoule and is considered more accurate. Data in the first column for 22 samples opened after 949 to 1550 d all ranged from  $1.3 \times 10^{-3}$  to  $9.7 \times 10^{-3} \text{ cm}^3 \text{ d}^{-1} \text{ cm}^{-2}$ , and only 7 of those are included here. Some of the pressure data were corrected for the vapor pressure of the propellant.

Another freezing-point depressant evaluated for hydrazine was hydrazinium azide. Rapid discoloration and pressure buildup were observed with hydrazine/hydrazinium azide mixtures in any type of steel, stainless or not. Moderate rates of gas evolution were measured for three such mixtures in aluminum-6061-T6 or titanium-6Al-4V [141, 142], although the rates were still higher than for neat hydrazine. Hydrazinium azide was also an ingredient in MHF-8. MHF-8 consisted of 72%  $\text{N}_2\text{H}_4$ , 19%  $\text{N}_5\text{H}_5$ , and approximately 9%  $\text{NH}_3$  [1712]. When MHF-8 was in contact with stainless steel, the solution turned pink within 8 h, which is an indication of leached metals. The rate of gas evolution of stainless-steel coupons in MHF-8 was also prohibitively high. Passivating treatments of CRES and protective treatments did not give the desired results.

**Ternary Blends.** It is difficult enough to find compatible materials for binary hydrazine propellants such as HPB-2400, but the task becomes even more difficult when metals that are resistant to ternary hydrazine/hydrazinium nitrate/water blends must be identified. Based on coupon and tank tests, it was found that Ti-6Al-4V and Ti-15V-3Al-3Cr-3Sn are suitable for such low-freezing propellant blends. Electropolished Al-1100 is marginally usable, but dissimilar Al alloys in contact, such as Al-1100/Al-2219, cannot be used [1680]. Tests at four different temperatures were used to derive an activation energy of the gas evolution process. This allows one to extrapolate to other propellant storage temperatures.

#### 5.3.7.1 Hydrogen Embrittlement of Metals in Hydrazine

Many metals, in particular refractory metals such as tantalum and zirconium, are susceptible to hydrogen embrittlement. Hydrazine is a reducing medium and likely to give off hydrogen under various conditions. Slow decomposition of liquid hydrazine during storage does not produce much hydrogen, but the small amount may be enough to embrittle metal [1713]. When excess hydrazine is used as a boiler feedwater additive for the removal of oxygen, it may decompose at the high temperatures and under the influence of radiation in the boiler, forming hydrogen gas and embrittling metals in the heat exchanger system, in particular in nuclear power plants.

#### 5.3.7.2 Compatibility of Hydrazine with Welding and Brazing Materials

Whenever possible, joints in tanks, lines, and components are electron beam welded or argon arc welded to avoid introducing additional dissimilar metals from welding rods. Frequently the size of the assembly or the delicacy of adjacent components does not allow welding.

Final assembly of hydrazine tanks, lines, valves, and thrusters in the spacecraft is then achieved by brazing, where a connection can be heated very rapidly by induction coils. Although only a small area is exposed to hydrazine where the braze compound wicks into the joint, compatibility of braze alloys must be assured before selecting such materials for hydrazine service.

Hydrazine decomposition caused by brazing alloys and their constituents was measured by capturing and analyzing the ammonia formed [1714]. The compatibility of hydrazine or Aerozine-50 with either the 82Au-18Ni alloy or the pure metals (Au or Ni) was equally poor as soon as the temperature exceeded 430 K. The amount of ammonia evolved was taken as the indication of hydrazine decomposition at 330 K. It would have been better to use the amount of nitrogen formed because some of the ammonia may remain dissolved in the propellant. A gold-nickel brazing alloy was blamed for a high rate of gas evolution observed with a 308L stiffening wire brazed to a CRES-304L diaphragm liner [1162]. Exposure of gold-based brazing alloys to Aerozine-50 at 339 K (150 °F) for 48 h did not result in leaching of excessive amounts of gold, nickel, or palladium [1715]. Pressure rise in a manometric vessel was not excessive, even in samples deliberately contaminated with 0.5 mass-% chloride ion or 0.5% ammonia.

The rate of gas evolution (normalized by the wetted surface area) from a Nioro (82Au/18Ni) braze joint in hydrazine at 322 K (120 °F) was two to three orders of magnitude higher than the rate from CRES-304 [1659, 1660]. If hydrazine, MMH, or UDMH becomes accidentally contaminated with halocarbons, the corrosion of braze joints and the resulting rate of gas evolution will be extremely bad [1060, 1711].

Sometimes the design requires very dissimilar metals to be joined by brazing. Inconel 600 has been vacuum-brazed to Ti-6Al-4V using a Ag-9Ga-9Pd braze alloy intended for a hydrazine pump [1716].

It should be noted that while nowadays one would be concerned about bringing hydrazine or hydrazine hydrate into contact with silver solder, the discoverer of hydrazine, Th. Curtius, was successful in distilling hydrazine hydrate in an apparatus where the retort and the condenser were made entirely of silver [1717].

## 5.4 Compatibility of Non-Metals with Hydrazine

Just as hydrazine and hydrazine derivatives may attack metals, hydrazines may also alter chemical bonds and mechanical properties of organic polymers. Non-metallic materials are needed as gaskets, seals, containment bladders, diaphragms, and lubricants. In addition, attempts have been made to replace metals with lighter-weight engineering thermoplastics in support structures and tank walls where they would be in constant contact with the hydrazines. It has been very difficult to find totally compatible materials for each of these applications. A summary of literature references dealing with non-metallic material compatibility tests with hydrazine, arranged by type of material and type of test, is available in [1718].

Quite often material compatibility data may be available for one of the three propellant hydrazines, but not for the hydrazine of interest. To a limited extent, it is possible to extrapolate from compatibility data for one hydrazine to another. For organic materials, the extrapolation is more difficult than for metals. Polymers found to be compatible with UDMH will most likely also be compatible with MMH and hydrazine; similarly, polymers found to be compatible with MMH will most likely also be compatible with hydrazine, but polymers known to be compatible with hydrazine may dissolve or swell in either MMH or UDMH. All polymers have some permeability for hydrazine(s). Hydrazine that had diffused into polymers and decomposed before exiting on the other side may cause the polymer to blister by forming nitrogen bubbles. See also [1719, 1720].

### 5.4.1 Gasket and Seal Materials for Hydrazine Service

#### 5.4.1.1 O-Rings

It may be difficult enough to find elastomers that satisfy requirements for hydrazine service at ambient temperatures. However, if the entire spacecraft is to be heat sterilized prior being loaded with hydrazine and sent off to another planet, material selection becomes a formidable problem [1678, 1679]. For repeated cycles at 408 K (275 °F), FEP Teflon with 20% glass filler and TFE Teflon O-ring seals have performed satisfactorily. Plasticized Kel-F has been specifically prohibited for use with hydrazine tank cars (MIL-R-87992, 29 Nov 1989).

One of the most widely used O-ring material is Parker Compound EPR 515-8 (or, as it is now called, E515-80). Besides carbon filler, it also contains zinc oxide and sulfur compounds. This material maintains its lubricity in hydrazine. However, because carbon was used in formulating this rubber, the rate of gas evolution was high [1162]. In most cases the O-rings do not contribute much surface area to the overall system and the gassing contribution is negligible. The O-rings are usually lubricated with Apiezon-L, a hydrocarbon grease, to avoid gouging them while they are slipped over valve nipples and adapters. In a 14-d immersion test evaluating four different O-ring materials in hydrazine at room temperature, Parker EPR XE2773-01 showed the least weight change and swelling and maintained its Duro hardness throughout the test. Parker EPR E515-80 O-rings were a close second. Parker Silicone S604-70 was swollen and did not meet acceptance criteria. E515-8 O-rings in hydrazine were tested at 333 and 353 K, and samples were taken after 69, 113, and 161 d [1721]. Changes in mechanical properties were evident at and above 353 K.

Viton O-rings in the oil seal cavity of the Space Shuttle Space Transportation System (STS) auxiliary power unit (APU) became embrittled when hydrazine leaked into the cavity. To correct this problem, they were replaced by Kalrez 1050 O-rings. Kalrez 1050 is a perfluoroelastomer and contains carbon black filler. A carbon-free variety called Kalrez 1045 is available and used for N<sub>2</sub>O<sub>4</sub> oxidizer systems. Kalrez 1045 O-rings caused exothermic reactions when in contact with hydrazine [1722]. Kalrez is often

used for MMH in bipropellant systems but is not suitable for hydrazine in monopropellant systems. See also [1723, 1724].

#### 5.4.1.2 Soft Valve Seats

Stillman rubber SR721-P80 and SR724-90, candidates for valve seat materials, were alternately exposed to hydrazine and air, water, or carbon dioxide [1725, 1726]. Earlier studies had shown that bladder elastomers after long immersion in hydrazine and drying would appear to become wet again on standing in air overnight, even though the specimens had been wiped dry the previous day. IR analysis proved the presence of carbazic acid in “sweat” droplets. During the repeated immersion/air exposure cycles with the two rubber samples, it was shown that the weight gain of SR724 leveled off at 3% by weight while SR721 continued to gain weight, up to 26% after 40 cycles. It is therefore undesirable to expose flight hardware to hydrazine and then to air prior to the actual launch. Similar observations were made with expulsion diaphragms for hydrazine tanks [1727].

A new rubber compound intended primarily for use as hydrazine thruster valve seats but adaptable to other engineering requirements was based on ethylene/propylene rubber reinforced with HYSTL pre-polymer resins and co-cured with peroxide [1728]. Compatibility tests in elevated-temperature hydrazine were used at the beginning of the program to identify compounding ingredients that did not react significantly with the propellant. Ingredients identified as hydrazine-compatible were then prepared in about 40 formulations and evaluated competitively in laboratory tests against a state-of-the-art hydrazine thruster seat compound in use on military and commercial satellites in the 1960s. These laboratory screening tests included measurements of swelling, compression set, and retention of properties following exposure to the propellant and to isopropyl alcohol valve cleaning fluid. At the conclusion of the program, the best compound was selected and designated AF-E-102.

Soft valve seat elastomers like AF-E-332 and AF-E-411 can absorb hydrazine, which is not totally removed from valve seats following an acceptance test procedure (ATP) firing at the thruster manufacturer. Subsequent exposure to air and carbon dioxide allows carbazates to form in and on the valve seat, where they will corrode adjacent metals. The time elapsed between breaking the vacuum in a vacuum tank after the ATP firing and flushing the valve with water in a clean room should be limited and controlled by process specification and inspection points. Some test specifications limit this time interval of air exposure to less than 30 min.

A variety of elastomers intended as valve seat materials for a new design Space Shuttle SRB APU Gas Generator Valve Module (GGVM) were tested, including polyether ether ketone (PEEK), Tefzel HT2004, various grades of IM Ryton (A, B, R-7, R-10), CM-X (hexafluoroisobutylene and vinylidene fluoride copolymer), IPC GR 5304, and TR-88 (the latter two are PPS and PTFE blends). Compressive creep/deformation tests in air and in hydrazine at room temperature and 366 K showed that hydrazine did not degrade the compression strength properties of Ryton. Ryton is

a polyphenylene sulfide (PPS) material. The GGVM valve used compression molded Tefzel HT2004 reinforced with 25% short glass fiber for a long time, but it cold flows. One grade of Tefzel was shown to catalyze the decomposition of hydrazine at 366 K [1722].

In the 1960s and early 1970s, some valves used a valve seat material called AF-E-102, until a better valve seat material became available in the form of AF-E-411. The development of AF-E-411 was a major breakthrough in the development of hydrazine-compatible elastomers. It was initially intended as an O-ring material but now has found its main application as a soft valve seat material. Its predecessor was AF-E-102, which had been developed under a NASA contract. The development of elastomers for soft valve seats often went hand in hand with the development of elastomers for propellant expulsion bladders and diaphragms [1729, 1730].

AF-E-102 had flown in O-rings and valves on a small number of satellites [1731–1733], before it was made obsolete by the improved AF-E-411 [1728, 1734]. AF-E-411 is a polymerized peroxide-cured ethylene propylene diene terpolymer (EPDM).

In parallel, valve seat and gasket materials were developed for use in NTO and Aerozine-50. One of the materials developed for this oxidizer application was AF-E-124D [1734]. AF-E-124D is a terpolymer of tetrafluoroethylene, perfluoromethyl vinyl ether, and perfluorophenyl vinyl ether, but it is not typically used for hydrazine.

AF-E-411 has been tested for compatibility with hydrazine at temperatures up to 477 K (400 °F) in a liquid-phase exothermicity test [1735, 1736]. This study was prompted by concern about the reactivity of AF-E-411 in the Space Shuttle Auxiliary Power Unit Gas Generator (APUGG) GGVM under hot restart conditions. Compatibility was tested in a liquid-phase exothermicity test like the one described in Section 5.2.1. A static immersion test was used to determine changes in tensile strength, elongation, hardness, weight, and dimensions. Samples of EPDM AF-E-411 were immersed in hydrazine for 30 d at 339 and 422 K (150 and 300 °F). There was no significant change in tensile strength, but increases in elongation at ultimate tension of 20–22% were measured. Hardness decreased 2% after the 339-K exposure and increased 11% after the 422-K exposure. Weight or dimensions changed less than 2%. The thickness increased by 1% in one dimension. When measuring 1% unidimensional expansion, volume swelling must be at least on the order of 3% (see the following discussion on swelling).

A compression-deflection set of AFE-411 seals in thrust chamber valves (TCVs) on 20-N thrusters may have caused internal leakage during long-life tests. It was believed that the compression-deflection set was caused by long-term fatigue. Dry compression-deflection tests were performed for 90 d on seal pucks made of AF-E-411, held in a simulated plunger and orifice that tied down the seal pucks like those used in the 20-N TCVs [1737]. The plunger press force was simulated by two weights: one for simulating the plunger spring force only and another for the maximum upper side pressure of the propellant valve.

#### 5.4.1.3 Swelling of Valve Seat Materials

Elastomers that are to be used as seat materials for soft seat valves must meet reproducible (preferably low or zero) swelling requirements and demonstrate dimensional stability. If the material swells too much after being exposed to hydrazine, it may close off the flow passage and restrict the travel of the valve poppet. However, AF-E-411 seems to have satisfactory dimensional stability in hydrazine and has been widely used for valve seats. Development tests have shown that the swelling of AF-E-411 in hydrazine is nominally less than 3% by volume. Despite the minor swelling, some valves with AF-E-411 may have different gas leakage rates depending on the history of exposure of the soft seal to liquids. If it was recently exposed to IPA or hydrazine, the valve would not leak any gas. If the seal is allowed to dry out prior to flight, it may leak gas [1738]. Gas leakage tests on valves that are already installed in a plumbed system may give misleading results, rejecting valves for gas leakage that would work perfectly fine in hydrazine.

Immersion of AF-E-411 in Freon-TF or trichloroethylene for 14 d at room temperature followed by air drying for 7 d causes permanent damage and permanent swelling [1734]. Distilled water caused no swelling, and IPA caused only minor swelling (after air drying). It is important to know the swelling of AF-E-411 in water or IPA in the *wet* state. Some reports show swelling data for Aerozine-50, but not for neat hydrazine. In the Aerozine-50 propellant, the elastomer had swollen 2.9% on removal from the liquid, and dimensional change remained at +1.9% even after drying in air for 7 d.

One case of gross material incompatibility was observed when a soft seat valve seat made from ethylene propylene rubber (EPR) (Parker Compound E-515-8) swelled so badly as to prevent any flow through the valve when the armature was actuated [1739]. Other materials tested in valve seats include Teflon, AF-E-102, and tungsten carbide.

It is sometimes difficult to correlate gas leakage measured on the dry valve prior to the test and the liquid hydrazine leakage during the test. Attempts have been made to establish a correlation between liquid hydrazine and gaseous nitrogen leakage rates of solenoid latching valves [1738, 1740]. It is believed that AF-E-411 swells just a little in the presence of liquid hydrazine, IPA, or water and then contracts again during drying. There is some hysteresis such that the elastomer may not return to its original dimensions after a swelling/drying cycle. Valves that flow correctly during short-term exposure to hydrazine (as during an ATP firing) may not flow correctly after extended soaking in hydrazine because the valve seat has more time to swell and the clearance between the poppet and the seat has diminished. Less clearance allows less propellant flow. Because the AF-E-411 disk (“hockey puck”) is typically pushed into a cavity (with only a small hole to allow escape of air), swelling can occur in only one direction, toward the opposing metal cone-shaped opening. In the dry state, the valve may leak gas. In the wet state, it may flow less than a nominal amount of liquid after it has

swollen. It is suspected that insufficient understanding of swelling phenomena has resulted in

- Unnecessary rejection of as-received valves, based on dry gas leakage tests, which would have performed perfectly well for liquid service after the initial wetting period
- Valves built to much tighter tolerances to meet unrealistic gas leakage requirements, which are more likely to swell shut accidentally while in liquid hydrazine service

It was necessary to obtain more accurate dilatometric data on AF-E-411 during exposure to hydrazine. Initial data of this type were generated when AF-E-411 and AF-E-332 were first developed [1741], but no additional systematic dilatometric studies were performed (or at least they were not published). MIL-R-83412A (30 Jun 1977) specifies three types of elastomers for seals, bladders, and valve seats for hydrazine service. The specification limits compression set but does not specify maximum swelling tolerated. The formulation shown in MIL-R-83412A for Type III valve seat material does not include Teflon powder, but according to other sources, AF-E-411 does contain 5% Teflon. Table 70 lists nominal compositions of the most frequently used elastomers AF-E-332 and AF-E-411. Questions have been raised about the upper temperature limit to which Teflon in hydrazine can be heated without splitting off fluoride ions and causing corrosion of adjacent metal parts. The hydrazinolysis of perfluoro polymers like Teflon requires additional study.

#### **5.4.1.4 Decontamination of Valves Following Hydrazine Service**

There is a question about the amount of hydrazine retained in AF-E-411 seats if flight thrusters with their flight valves attached as one unit are acceptance tested and subsequently decontaminated. Small amounts of hydrazine may diffuse into the elastomer and may not be completely removed during the typical post-ATP decontamination. Although AF-E-411 swells less in hydrazine than any other valve soft seat material developed so far, the elastomer may swell sufficiently during ATP to cause different valve gas leakage response after the ATP test. Valves may pass the gas leakage test immediately after ATP but fail it after the valve seat has completely dried out and shrunk back to its original shape.

There is concern that hydrazine cannot be completely removed from valve seats in TCVs following ATP. Exposure to air will cause carbazate formation and zinc and calcium leaching similar to the problem observed with pre-tested hydrazine-soaked propellant expulsion diaphragms on some satellite reaction control system (RCS) tanks [1727].

#### **5.4.1.5 Other Problems and Precautions with Valve Seat Materials**

As-manufactured AF-E-411 may have oil oozing out of it that may cause valves to stick if they are not used soon after purchase. Attempts have been made to extract the oil

with a solvent. The elastomer expands in hydrocarbon solvents to twice its original size but returns to the original size after all solvent is removed.

AF-E-411 should not be exposed to hot dry air. This is a concern if solenoid valves, in particular latch valves, are inadvertently activated in the dry state prior to launch of a spacecraft. It was once common practice to check out the electric circuitry in assembled spacecraft by dry-cycling the valves. (This is a bad practice; in addition to the risk of overheating, some metal-to-metal sliding surfaces might gall in the dry state.) Some latch valves could reach 444 K in orbit if one coil is energized, or they might even heat to 533 K if both coils are inadvertently energized (if no propellant is flowing or this branch of the system is isolated). AF-E-411 should not be heated in air to above 344 K or in nitrogen above 380 K.

There is concern that heating Teflon-containing elastomers in hydrazine to above 422 K (300 °F) may hydrazinolyze the Teflon and result in the local formation of hydrofluoric acid and hydrazinium fluoride, which in turn would attack any steel (stainless or not) in the vicinity of the valve seat. Several fluorinated elastomers tested per NHB 8060.1C Test 15 showed significant increases of fluoride in the off-loaded hydrazine [1663, 1664].

#### 5.4.1.6 Graphite as Seal Material

The STS APU hydrazine and lubricant pumps used a graphite rotary seal. The seal part was machined to achieve ultimate dimensions only after exposure to hydrazine because it swells during hydrazine exposure [1742–1745]. Hydrazine was dropped to the fuel pump usually a few days prior to launch to allow the seal to achieve its proper dimensions before the unit was pressurized.

### 5.4.2 Polymers for Structural Components in Satellites

By way of elimination, materials known to be incompatible with hydrazines should also be listed here. Polyester polymers are *not* compatible with hydrazine. In fact, carboxyl groups in polyethyleneglycol terephthalate are routinely analyzed by hydrazinolysis because the reaction goes to completion quantitatively. Hydrazine has been patented as a solvent for removal and etching of polyimide films, which are otherwise very inert to all common solvents and thermally extremely resistant. Hydrazine hydrate reacts with polyvinyl chloride (PVC). The reaction products of hydrazine and PVC oxidize when exposed to air. Cellulose acetate, Nylon, Mylar, Saran, Silastic LS-53, Epon, and Tygon were listed among non-compatible elastomers for valves [1637]. Polyvinyl alcohol or Kel-F 500 dissolved in hydrazine in less than 2 h.

Cellulose acetate, polyester, polystyrene, polyvinylalcohol, or Saran are *not* compatible with hydrazine [1636]. Epoxy, ethyl cellulose, furan resin, Hycar, Kel-F, Lucite, melamine formaldehyde, Nylon, phenolic, Silastic, or Tygon are said to be only conditionally (short-term) compatible with hydrazine or hydrazine hydrate by some

sources, but who would believe them? Anyone who has seen Nylon dissolve in anhydrous hydrazine knows that it is not compatible in any conditions.

A two-volume report lists hydrazine compatibility data of 39 polymer samples at 313, 333, and 353 K [1746, 1747]. Terylene dissolved in hydrazine within a few minutes. Kapton polyimide film dissolved just as quickly. The following polymers were found to be incompatible with hydrazine: Nylon cloth embrittled after 30 d. Viton (polyhexafluoropropylene/vinylidene fluoride) expanded to twice the original size and blistered within less than a day. PVC turned yellow and brown within 6 d. After 29 d the hydrazine had become syrupy and contained large transparent crystals. Different grades of neoprene blistered and became embrittled. Acrylonitrile-butadiene (Hycar nitrile rubber) did not show immediate visual changes but became badly embrittled after 344 d. Likewise, styrene/butadiene rubber (SBR) had lost both tensile strength and elongation after 344 d; CNR nitroso rubber disintegrated within 4 d. Fluorel LCS 2160 (Dowty 2055) disintegrated within 10 min. Several silicone rubbers, including RTV 731 and Silastoseal B, did not survive hydrazine exposure. On all these materials, weight changes were recorded during the entire exposure (up to 130 d). Initially many materials gained weight from hydrazine absorption and swelled. After some time, the samples lost weight again as they began to disintegrate and dissolve in hydrazine. The following polymers were classified as compatible, and extensive mechanical data were gathered after hydrazine exposure for up to 1130 d: Parker EPR 515, EPR Dowty IM 1333, and silica filled-butyl rubber. Polyethylene and polypropylene are only conditionally acceptable. Polyethylene totally immersed in hydrazine did not change much over several years, but hydrazine stored in polyethylene bottles caused the plastic to blister.

A Mylar (polyethylene terephthalate) sensor disc was used as a leak detection device in a double-walled hydrazine tank. If the internal shell of a hydrazine tank had leaked, the Mylar would have dissolved and allowed movement of a spring-loaded magnet, which would have triggered a Reed switch on the outside of the tank and triggered an alarm.

The mechanical properties of polyethylene were unaffected by immersion in 64%  $\text{N}_2\text{H}_4$  (= HH100) for up to 90 d at up to 333 K [1748]. The hydrazine assay was unchanged, and there was no residue buildup in the hydrazine hydrate. Polypropylene was just as compatible, but PVC and nylon were attacked by hydrazine hydrate. However, 64%  $\text{N}_2\text{H}_4$  (= HH100) sold and shipped in polyethylene bottles in cardboard boxes was found to permeate the polymer and destroy the cardboard after years of storage on the shelf in an industrial building, narrowly avoiding ignition. HDPE (plastic bottles) will form blisters because hydrazine permeates into it, but gas does not diffuse out.

Occasionally hydrazine or MMH is spilled on the outside of a spacecraft during a fueling mishap. Material immersion/impingement tests for such short-term exposure have been conducted for many materials that ordinarily would not be exposed to hydrazine.

Molded parts made from thermoplastic resins can be manufactured in the near-net shape ultimate dimensions, which require no further machining, thus leading to cost savings. The trouble was that until recently, very little was known about the compatibility of thermoplastic resins with rocket propellants because many of these materials have become available only within the past four decades. Ten engineering thermoplastics were tested in anhydrous hydrazine for suitability in an Aerozine-50 application, as summarized in Table 68.

Polycyanurates formed by heating bisphenol-A monomers containing cyanate ( $-\text{OCN}$ ) groups are a new class of thermosetting polymers that can be worked into high-strength composites. These have higher toughness, reduced moisture absorption, and improved dimensional stability compared to conventional epoxy resins. They are now used for primary bus structures, tubes, struts, solar-array panels, and many other structural components in satellites such as MILSATCOM, AXAF, and CLEMENTINE. Spill tests with exposure times of 2 min. to 24 h indicated that polycyanurate resins and composites exposed to hydrazine will lose strength rapidly and become partially dissolved [1750]. The polycyanurate resins did not fare any better than a conventional epoxy resin that was also exposed to hydrazine for comparison. Epoxy/carbon composites seemed to offer better resistance to hydrazine and polycyanurate/carbon composites were more resistant to NTO oxidizer.

### 5.4.3 Lubricants for Hydrazine Service

Several lubricants were tested as reported in in the chapter “Methylhydrazine,” for exothermic reactions with hydrazine or MMH. Exothermic reactions would indicate incompatibility of these materials with hydrazine(s) and advise against their use.

#### 5.4.3.1 Lubricant Oils and Greases

Hydrazine itself is a very poor lubricant, and many metal-to-metal rotary seals or sliding seals in pumps, flow meters, or valves for hydrazine service have failed for this reason. The problem appears to be less severe with MMH or UDMH. A low-load, short-duration ball bearing test failed in hydrazine due to lack of lubrication [1637]. Most wet lubricants are either washed off or attacked by hydrazine. A perfluoropolyether grease made by DuPont, Krytox 240, appears to be compatible with hydrazine and MMH based on gas evolution measurements and lack of corrosion of the lubricated metals. Krytox greases contain a polymer of tetrafluoroethylene and perfluoroalkylpolyethers of the general formula  $\text{F}[\text{CF}(\text{CF}_3)\text{CF}_2\text{O}]_n\text{CF}_2\text{CF}_3$ .

Eight different metal samples coated with Krytox 240AC were included in a 10-year storage test with hydrazine [1160, 1161]. Another type of Krytox tested was Krytox 143AB [1638]. However, earlier recommendations of Krytox ignored the danger of hydrazinolysis at higher temperatures (when Krytox droplets are swept into the catalyst bed with hydrazine) and subsequently fluoride killing the catalyst just as Freon did (see *Encyclopedia of Monopropellants*, in the chapter “Hydrazine Monopropellants”).

**Table 68:** Results of hydrazine immersion tests of engineering thermoplastics.

| Thermoplastic        | Type of polymer                     | Yield strength, MPa, before | Yield strength, MPa, after | Yield strength change, % | Ultimate tensile strength, MPa, before | Ultimate tensile strength, MPa, after | Ultimate tensile strength change, % | Weight change, % (estimated) |

Data source: [1749]. 12-d immersion, immersion temperature not defined.

Krytox 240AC was widely used for servicing the Space Shuttle Orbital Maneuvering System (OMS)/RCS bipropellant systems and does not interfere with the combustion process in a bipropellant engine. Occasionally, more than generously applied Krytox 240AC is swept away and accidentally also finds its way into monopropellant hydrazine systems for which Krytox is not recommended. Excess Krytox 240AC is not soluble in hydrazine but may wash off in flowing hydrazine and gets carried along as floating globs of grease. There is concern that the fluoride formed by reductive pyrolysis in the monopropellant reactor may result in corrosion of metals in the injector or deactivation of Shell 405 catalyst. A coupon of CRES-304L coated with Krytox 240 AC and subjected to Test 15 of NASA 8060.1C in hydrazine (48 h at 344 K) showed higher gas evolution on the coated sample when an uncoated piece of CRES-304L was the reference coupon. The off-loaded hydrazine from the Krytox samples should have been analyzed for fluoride like fluorinated elastomers tested earlier per NHB 8060.1C Test 15, which showed significant increases of fluoride in the off-loaded hydrazine [1663, 1664]. Dow Corning Silicone Oil 710 was used to disperse hydrazine droplets at freezing temperatures, apparently without adverse reactions [114].

The space shuttle APU turbine and gear box was lubricated with Mobil Jet II per MIL-L-23699, a phosphate ester, which was not intended to come in contact with hydrazine. The hydrazine fuel pump and the lubrication oil pump were on the same drive shaft, and the two fluids were separated only by a pair of rotating seals. Early designs did not prevent hydrazine from leaking across the rotating seal and contaminating the lube oil, forming a wax-like precipitate (pentaerythritol) by hydrazinolysis of the phosphate ester in the synthetic oil, clogging the oil filter, and forcing the bypass relief valve open. This happened on STS-2 and again on STS-4, causing launch aborts [1742]. At one time, it was considered to add hydrazine-scavenging additives to the oil [1744]. Later, the two seals, which used to drain into a common cavity, were changed to have separate seal drain cavities and collection bottles in which eventual leakage was collected separately and removed after each flight. The pressure in the drain bottles was measured. A similar incompatibility occurred early during the development of the STS APU with ammonia exhaust gas from the turbine housing leaking into the hydraulic fluid. Ammonia reacted with an additive in the hydraulic fluid and formed a silt, which clogged the hydraulic fluid filters. The hydraulic fluid specification is MIL-H-83282, which is a synthetic hydrocarbon (to reduce fire hazards).

A thin film of Apiezon-L is often used to lubricate O-rings prior to sliding them over valve stems or hydrazine engines. Apiezon-L is a hydrocarbon-based, halogen-free lubricant.

#### 5.4.3.2 Dry Lubricants

Most dry lubricants are attacked and removed by hydrazine. Electrofilm 1000G and Lubeco 2029-3 were said to be partially compatible, but wear life was reduced once the unit was exposed to hydrazine [1637]. The rams in pyro valves (e.g., Siebel Air P/N 55-02462-5) were at one time lubricated with dry lubricants such as molybdenum

disulfide to facilitate movement of the ram. Unfortunately, molybdenum disulfide is highly reactive with hydrazine, resulting in a rapid rate of gas evolution by hydrazine decomposition and possible poisoning of the iridium catalyst by sulfide released in catalytic thrusters. In a ground test simulating a 2-month hold on the launch pad, pyro valves with MoS<sub>2</sub> dry lubricant were filled with hydrazine and tested in the unfired or fired state, and in both cases the closed-off section rapidly overpressurized and the hydrazine turned black. Molybdenum disulfide may also have been used by some manufacturers as a lubricant in extruding titanium wire and become embedded in the surface of the wire, resulting in high rates of gas evolution when mesh woven from the contaminated wire came in contact with hydrazine. Such wire may have been used inadvertently in surface tension propellant management devices for MMH, hydrazine, and NTO.

Two greases and two dry lubricants were tested for compatibility with hydrazine for 48 h at 416 K when coated on a 17-7PH coupon. Apiezon-L (a petrolatum hydrocarbon grease) and Microseal-100-1 (graphite) were deemed acceptable, but Braycote 3L38RP grease and Microseal-200-1 (MoS<sub>2</sub>) dry lubricant were not acceptable.

Insufficient information is available on graphite as a dry lubricant. One would hesitate to allow all brands of dry lubricants with graphite to be used on hydrazine systems. It is known that hydrazine may cause graphite to swell because it can intercalate between the layers of carbon atoms. Graphite seals on the STS APU fuel pump had to be wetted with hydrazine several days ahead of a flight so they would swell to the intended dimensions and provide a tight seal.

#### 5.4.4 Propellant Expulsion Diaphragms and Bladders

For a propellant expulsion bladder or diaphragm it is important that the material be strong and flexible, remain flexible under conditions of propellant exposure and radiation exposure, have low permeability to propellant liquid, propellant vapors, and pressurant gases, and not leach any contaminants into the propellant. A summary of contamination incidents caused by contaminant leaching from diaphragms is given in Section 5.4.4.2. The chemistry and manufacturing engineering of expulsion diaphragm and bladder production have made enormous progress over the past six decades, allowing hydrazine to be used in many launch vehicle and satellite applications.

##### 5.4.4.1 General Elastomer Mechanical Properties and Gas Evolution

In the early days of hydrazine flight system development, hydrazine stability in elastomer expulsion devices was measured only in weeks [1751, 1752]. For instance, a butyl rubber expulsion bladder was used on the RANGER 3 spacecraft, where storability was asserted to be better than 9–13 weeks. Although EPR-5 showed no measurable Ae-50 permeation, Butyl-7 allowed 0.7% of the propellant to escape after 7 d. Among six candidate formulations based on *cis*-1,3-polybutadiene, Butyl-218, Hydropol, or EPR, the

latter showed the lowest swelling (16%) after immersion in Ae-50 at 344 K (160 °F) for 30 d. Other rubber formulations swelled 40%. Hydrazine immersion tests with 12 different elastomers showed that E515-8 and butyl rubbers FR-6-60-26 and SR-722-70 were among the worst for gas evolution but at the time were the only ones with sufficient manufacturing background that could be formed into bladders and diaphragms to meet launch dates. Despite considerable concern about pressure rise, FR-6-60-26 was chosen for the MARINER missions.

The carbon-black filler material in EPR-132 was found to be responsible for the high rate of gas evolution when EPR-132 samples were immersed in hydrazine [1655, 1656]. The rate of gas evolution with a sample that did not contain carbon black was much lower than with the standard grade of EPR-132 (100 parts Enjay 404, 50 parts carbon black, 10 parts Di-cup 40C [= 40% dicumyl peroxide and 60%  $\text{CaCO}_3$ ]). The rate of gas evolution for several EPR samples tested was  $0.011\text{--}0.094\text{ cm}^3\text{ cm}^{-2}\text{ day}^{-1}$  ( $0.0044\text{--}0.037\text{ in.}^3\text{ d}^{-1}\text{ in.}^{-2}$ ).

Standard Teflon/aluminum laminate bladders employed as NTO and MMH zero-g propellant management devices on the MARINER Mars 71 space probe failed because of cracks and tears near an aluminum seal ring which formed the mouth of the bladder [1753]. These failures occurred during flight-acceptance tests with inert solvents (Freon-TF and isopropanol) used as simulant fluids. It was found that one of the laminate polymers, FEP 120, was particularly solvent-sensitive, and it was then eliminated from future laminates for expulsion bladders.

Over the past six decades, substantial effort has gone into the development of hydrazine-compatible elastomers for expulsion bladders and diaphragms. It is only after reviewing all that literature generated during the 1960s that one begins to appreciate the availability and properties of AF-E-332, which was the mainstay diaphragm material for hydrazine for several decades after first being introduced on the market. Compounding studies directed at improving the compatibility and permeability of EPR [1754] and EPT rubbers evaluated 10 new formulations [1755]; EPR-132 was run along as a baseline. Non-carbon fillers (clay, fumed silica Silene-D) gave lower tensile strengths. Terpolymer formulations were less resilient than copolymer formulations. Bladders for MARINER 69 were produced from Butyl Compound FR-6-60-26. In addition, bladders were also produced from Compound 10, a forerunner of EPT-10. It was during this development effort that passivation by presoak in hydrazine, then discarding the hydrazine used in the presoak, was first recommended (a practice followed for several years, but which later led to other complications).

A material called HYSTL offered attractive processing characteristics and showed good compatibility with hydrazine and hydrazine-type fuels. Co-curing HYSTL and EPDM gave elastomers of superior mechanical and hydrazine compatibility properties suitable for diaphragms as well as valve seats and gaskets [1730].

Continued efforts resulted in the development of ethylene-propylene-terpolymer (= EPT-10) bladders that were used on numerous flight vehicles. Polymers filled with higher silicon dioxide levels exhibited better hydrazine compatibility. Forty-three

other rubber formulations, including butyl rubber, were tested, but EPT-10 performed best [1756]. Typically, EPT showed a 13% loss in tensile strength, 70% increase in elongation, 30% loss in modulus, and 20% swelling after exposure to hydrazine. After a few years, most flight applications had switched to AF-E-332, which was superior to EPT-10 in terms of physical properties [1757]. AF-E-332 was developed by the Applied Chemistry Department of TRW Systems Group under contract from the Air Force Materials Laboratory [1758–1760]. Elastomers developed for service with hydrazine included AF-E-332 (EPDM rubber) for hydrazine positive expulsion devices, AF-E-411 (EPDM rubber) for hydrazine valve seals, and AF-E-124D (perfluorinated polymer) for both hydrazine and NTO seals and positive expulsion devices. Tests ranged from simple laboratory screening to complete design verification testing of a full-size AF-E-332 positive expulsion bladder. The initial version AF-E-332-6 demonstrated the concept of co-reacting elastomers with low-molecular-weight 1,2-polybutadiene resin. An advanced version AF-E-332-11 later became the mainstay of expulsion elastomer production for propellant tanks for several decades. The original formulation of AF-E-332 was based on the use of DuPont Nordel 1040, an ethylene-propylene-diene-modified (EPDM) terpolymer (EPT) but had problems with low-molecular-weight oligomers extracting into the hydrazine and contaminating and plugging small thrusters. To overcome this problem, the APT was first extracted with boiling methanol, then 2-butanone. DuPont later produced a Nordel 1035 that did not have the low-molecular-weight oligomers, and it was the main polymer for many years until DuPont ceased manufacturing Nordel 1035. Based on lengthy development tests, a 50 : 50 mixture of Nordel 1440 and Nordel 2744 gave an elastomer identical to that obtained in earlier years with Nordel 1635. This history of AF-E-332 modifications and ingredient substitutions may be important when comparing contaminant-leaching properties of AF-E-332 measured at different organizations over a span of several decades. Contaminant leaching may depend on the quality of the binder that is holding the filler particles together. Side-by-side 11-year storage tests of hydrazine in a titanium/EPT-10 and a CRES/AF-E-332 tank showed that both elastomers suffered a reduction in tensile strength of 15–30% [1761].

EPDM elastomer formulations like AF-E-332, but without the calcium oxide and zinc oxide fillers, have been developed in other countries, but improvements over AF-E-332 have not been demonstrated [1762]. The specific gas generation rate of these materials dropped off very sharply during the 670 h of an immersion test at 343 K. Fluor-elastomers were expected to be resistant to hydrazine as well as NTO, but permeability problems persisted [1763].

#### **5.4.4.2 Contaminants Leached from Diaphragms and Bladders**

Both EPT-10 and AF-E-332 have had their share of contaminant-leaching problems. The most troublesome contaminants leached were zinc and silica (and other silicon compounds). It was observed that when EPT-10 elastomer was immersed in hydrazine, some of the Silene-D silica was shed from the rubber and was visible as white particu-

late matter floating in the liquid [1635]. This observation led to a pre-flight pre-soak for 168 h of EPT-10 diaphragms in hydrazine in order to remove some of the leachable silica (and sulfur?) prior to flight. In some applications, the pre-flight soak was combined with the measurement of the pressure rise rate as an indication of cleanliness of the diaphragm. The pressure rise rate was expressed as a diaphragm activity index (DAI). Unfortunately, hydrazine was retained in the elastomer, and some diaphragms and tanks were subsequently exposed to air and they absorbed carbon dioxide, making the zinc-leaching problem even worse [1727].

Six EPT-10 diaphragms representing two different methods of post-DAI decontamination and two controls were immersed in pure hydrazine, and leached contaminants were analyzed. It was shown that the DAI method that only vacuum dried at room temperature and  $10^{-5}$  mm Hg for 24 h resulted in the highest zinc leaching, whereas diaphragms baked for 12 to 36 h at 310 K in air caused less zinc leaching. All diaphragms had seen air exposure of several months between DAI and the leaching test. During this period, they must have picked up significant amounts of  $\text{CO}_2$  and formed zinc carbazate. Based on parallel coupon tests under controlled conditions, AF-E-332 and Parker EPR-515-8 were less susceptible to zinc leaching than EPT-10. Noticeable amounts of zinc could be leached from Parker EPR-515-8.

AF-E-332 normally caused little propellant contamination (NVR) when immersed in hydrazine. Shortly after AF-E-332 became first available, nine 22-in. diaphragms were molded from two different AF-E-332 compositions and subjected to soak tests and expulsion cycles in heavy-duty bolt-up tanks. After three of the diaphragms were subjected to a 50-d soak in hydrazine, the propellant remained virtually unchanged in NVR [1757]. Very little zinc and calcium was leached, in contrast to EPT-10, where the NVR (mostly Zn and Ca) could reach 140 ppm in a very short time. When studying hydrazine contamination caused by materials leached from AF-E-332 bladders, it was noted that large amounts of silicon were leached [1764]. Other trace contaminants analyzed included zinc, magnesium, calcium, and aluminum. The amount of silicon leached is proportional to the surface : volume ratio, the soak temperature, and the immersion time. Dynamic testing at less than 100000 expulsion cycles also increased the rate of silicon transfer. The amount of silica leached at different temperatures seemed to fit into an Arrhenius rate chart when the logarithm of the rate was plotted versus reciprocal absolute temperature. The source of silicon is most likely a hydrophobic grade of fumed silica used as filler for the elastomer. The silanization of particulate silica forms a protective coating that inhibits wetting (and extraction) by hydrazine. It is not known whether or not ester-like  $-\text{Si}-\text{O}-\text{Si}(\text{CH}_3)_2-\text{O}-$  and  $-\text{Si}-\text{O}-\text{Si}(\text{CH}_3)_3$  groups protruding from the surface are subject to hydrazinolysis or hydrolysis in the presence of hydrazine. If they are, some of the leached silicon may be in the form of volatile silicon organic compounds. Silicon analysis in hydrazine is a difficult task because unknown amounts of silicon may be leached from glassware commonly used for analytical work. Side-by-side comparison of analyses done in glassware versus Teflon labware showed that the blank sample handled in glass had 3.7 ppm Si versus 1.0 ppm in Teflon. Three

different analytical methods for Si analysis were compared: colorimetry, atomic absorption inhibition titrimetry, and atomic absorption with a nitrous oxide/acetylene flame [1764]. Based on a round-robin with three participating laboratories, agreement among the different laboratories was good once the samples had been transferred to aqueous solutions. There was more scatter among samples doped with colloidal silica compared to samples doped with sodium silicate. The main differences were caused by sample concentration methods while removing the hydrazine and digesting the residue. Calculations of the volume occupied by silica residues left in the injector of a rocket engine after each pulse showed that even very small silica concentrations are enough to block injector passages in a monopropellant thruster. See also Section 6.1.5.

Analysis of hydrazine off-loaded after side-by-side 11-year storage tests of hydrazine in a titanium/EPT-10 and a CRES/AF-E-332 tank showed that the silica content in the AF-E-332 tank had increased to 10.9 ppm, whereas silica concentration in the propellant from the EPT-10 tank remained below the detection limit of 1 ppm [1761]. However, the non-volatile residue in the EPT-10 tank increased to 100 ppm, significantly above the specification limit.

Hydrazine sampled during a FLTSATCOM flight tank storage test showed a gradual increase in leached Zn, Ca, Si, and NVR as summarized in Table 69. Fluctuations may be caused by a different mode of agitation of the tank before taking a sample.

**Table 69:** Contaminant leaching from AF-E-332 at 322 K (120 °F).

| Time, weeks    | 0      | 7      | 15   | 31   |
|----------------|--------|--------|------|------|
| NVR, mg/100 mL | 3.1    | 3.1    | 38.7 | 41.5 |
| Zn, ppm        | < 0.08 | < 0.08 | 0.11 | 0.19 |
| Ca, ppm        | 0.18   | 0.18   | 0.21 | 0.40 |
| Si, ppm        | 0.64   | 0.30   | —    | 1.92 |

Data source: [1765]

There has been continued concern about silica and other particles shed from AF-E-332 during immersion in hydrazine. Several in-orbit anomalies of European satellites of the ECS, TELECOM, and OTS series have been blamed on silica leaching. The failure mechanism, feed tube clogging or catalyst deactivation, has been reproduced in ground testing. As the result of various silica problems, several organizations had started development of silica-free elastomers for hydrazine expulsion tanks. Silica can be replaced by alumina as the filler. The nominal compositions of AF-E-332 and AF-E-411 are compared in Table 70.

To be accurate, the complete designation of AF-E-332 in the early days was AF-E-332-11, where the -11 indicated the variation of curing agents and compounds used in making the elastomer. The -11 was the most successful compound in replacing EPT-10 and was used exclusively from then on. The -12 variant did not contain any zinc oxide

**Table 70:** Nominal composition of AF-E-332 and AF-E-411 elastomers.

(which was responsible for some of the problems observed with flight systems). It was suspected that air exposure of AF-E-332 would also enhance silica shedding. There is no indication that air exposure aggravates subsequent silica shedding on first-time exposure of the elastomer to hydrazine.

A hydrazine propellant blend called HPB-2012 and consisting of 20% HN, 12% water, and 68% hydrazine is not compatible with AF-E-332, and it is suspected that it will dissolve metal oxide fillers [1766]. The mechanical properties of AF-E-332 exposed to HPB-2012 or MMH for 2 months at room temperature degraded to the point where some samples broke when a static load of 75% of the breaking strength of an unexposed control was applied to the post-test dried samples. Hydrazine or UDMH did not damage the elastomer to the same extent. This loss of strength has been blamed on the leaching of fillers like CaO or ZnO. Unfilled EPDM was weaker than AF-E-332 to start with, but its mechanical properties were not affected by the HPB-2012 propellant exposure.

#### 5.4.4.3 Multi-Cycle Applications of Diaphragms and Bladders

Typical space flight tanks get filled with hydrazine only once and go through only one reversal cycle. An exception were the three Space Shuttle Orbiter APU hydrazine tanks, which were qualified for at least 20 missions. A program was conducted predicting useful lifetimes of elastomer diaphragms with multiple reversions in hydrazine tanks [1767, 1768]. Previous space applications of diaphragm tanks required only a limited number of diaphragm reversals and filling-draining cycles; however, the Space Shuttle APU tanks had to withstand numerous flexing cycles. Therefore, emphasis has been placed on dynamic testing of materials for hydrazine diaphragms [1769–1771].

When AF-E-332 was first selected for STS APUGG, NASA contractors were concerned about silica shedding from AF-E-332. There were insufficient data available at that time to assess the effects of silica shedding on the APU. It has become apparent in the meantime that the wear products from the teeth of the gear pump outweigh any

other particulate contamination that may be in the fuel entering the APUGG, and the concern about silica contamination on Space Shuttle has gone away.

#### 5.4.4.4 Gas and Propellant Permeability Through Elastomers

Positive expulsion PMDs, such as tank bladders or diaphragms, must maintain the propellant side of the tank free of pressurant gas either dissolved or in a bubble gas phase in order to function properly. The pressurant gas, which surrounds the bladder and provides the pressure necessary to force the liquid propellant from the tank, may diffuse through the bladder or diaphragm wall and, in time, will saturate the propellant. This results in poor engine performance depending on the level of contamination and the disposition of the gas, i.e., dissolved or in the form of bubbles, on the liquid side of the PMD. In addition, propellant vapor can diffuse in the opposite direction through the polymer into the pressurant gas space. Not all components on the gas side may be compatible with propellant vapors. Laminated (“sandwiched”) Teflon-metal foil-Teflon composite bladder structure had been used during the early years of hydrazine applications in space propulsion until improved and compatible polymers became available. Without the thin metal foil sandwiched between the Teflon layers, the diffusion rate of propellant and pressurant would be excessive for long-term space missions. With a perfect (no holes) metal foil barrier, the diffusion rate should be essentially zero. However, small pin holes in the foil resulting from handling of the bladder or imperfect manufacture of the sandwich structure may be expected to occur in assembled expulsion bladder systems. The permeation rates of pressurant gases, hydrazine, or NTO were measured [1772, 1773]. The pressurant gas solubility and rate of diffusion of gases in liquid propellants were measured and entered into a model for propellant saturation.

In a scaled-down propellant tank, permeability of AF-E-332 toward hydrazine was measured during 130-d storage tests to simulate actual conditions as closely as possible. At 308 K, less than 0.002% of the propellant permeated, whereas at 358 K, approximately 0.02% permeated through the bladder [1774].

Out of 22 plastic materials tested for compatibility with hydrazine/HN/water mixtures, only Teflon, Kel-F, and polyethylene showed negligible weight change [242]. Polyvinylidene fluoride (PVF, Kynar) suffered some embrittlement on long contact with hydrazine [1775]. For short-term missions, PVF bladders may be acceptable if permeability is not an important factor. In the NHB 8060.1C Test 15, Kynar 460 had a low rate of gas evolution, but increased the fluoride content of the off-loaded hydrazine to 2400 ppm (!) [1661–1663]. It may also cause problems in MMH in contact with steel [1776]. In the same test, Kel-F 81 had a low rate of gas evolution but also increased the fluoride content to 213 ppm, which makes it unacceptable for hydrazine monopropellant use. Rulon J changed color, and the hydrazine turned brown during a 48-h test at 344 K [1662]. Seamless Teflon positive expulsion bladders were used for MMH and Aerozine-50 propellants on APOLLO Command Module, Service Module, Lunar Descent Module, and even on the S-IVB upper stage [1777].

One of the applications for which Teflon and other polymers were evaluated was the advanced liquid propulsion system (ALPS) developed by JPL, although it has never seen flight use. Teflon had been evaluated extensively as a bladder and diaphragm material in the early days of hydrazine rocket propulsion, but it was found to cold flow in the bead holding it in place; it was too stiff and had high permeability for hydrazine [1778].

Long-term tank storage tests have often found hydrazine on the pressurant side (the “wrong” side) of positive expulsion diaphragms [1761]. The situation becomes more serious if operational spacecraft are flying with hydrazine on the “wrong” side of the diaphragm because the pressurant gas lines are usually not heated and hydrazine may freeze if the pressurant gas line temperature drops below 270 K. One of the hydrazine APU tanks removed from the shuttle OV 102 (Columbia) had substantial quantities of liquid hydrazine on the nitrogen side of the tank [1769–1771]. The hydrazine was analyzed and contained 2.6% water and 300 ppm isopropanol.

Hydrazine vapor permeating through the propellant tank diaphragms was suspected of diffusing through the pressurant gas system of a Defense Meteorological Satellite Program (DMSP) satellite and may have come into contact with components that were not compatible with hydrazine [1779].

Nitrogen permeation through EPT-10 and hydrazine propellant saturation with  $\text{GN}_2$  was suspected as the cause for a 5-psi pressure drop in the freshly fueled RCS of the SCATHA satellite during a 2-d thermostatted pre-launch hold and observation period [1780]. It is surprising that propellant saturation should occur in such a short period despite the barrier of the elastomer diaphragm.

There are at least two areas in aerospace technology where hydrazine permeation through elastomers is of practical interest: the permeation of positive expulsion bladders and diaphragms discussed earlier and permeation through protective clothing discussed in Section 7.6.2. There are two methods for permeability testing, a transient method in which the time to breakthrough is measured, or a steady-state method in which the permeation rate is allowed to stabilize and the permeate is measured over a constant time interval. In Europe, a test method for permeation through elastomers (DIN 53580) has been proposed for propellant permeation testing of new diaphragm materials. This method was used to test perfluoro polymer TFM-PFA-TFM-PFA laminates (PFA facing the fluid side) with MON-1, MMH, and hydrazine [1781]. PFA is an abbreviation for perfluoroalkoxy polymers. TFM and PFA are PTFE co-polymers using perfluoropropylene-vinyl-ether (PPVE) as co-monomer. TFM is a copolymer with about 0.1% PPVE and PFA is a copolymer with 3–15% PPVE. TFM is similar to PTFE but with higher porosity and elongation and with a high degree of weldability. PFA is a melt-processable thermoplastic with chemical resistance like PTFE. It has much lower porosity and is translucent. The emphasis in this ESA-sponsored program was to develop silica-free expulsion diaphragms for satellite tanks. Test methods were supported by mathematical modeling of gas and propellant permeation.

## 5.5 Hydrazine Vapor Compatibility at Ambient Pressure

The gas evolution of hydrazine vapor at low partial pressures (below saturation pressure) decomposing on the internal surface of propellant tanks intended for liquid hydrazine service has been used as a method for determining the cleanliness of tanks without inserting a fiber optic probe and without cutting the tanks open [1500, 1501]. This is a useful non-destructive examination technique that could be used for the inspection of new tanks on the assembly line or for trouble shooting of tanks and completely assembled systems suspect of harboring contamination (e.g., rust, weld scale, Freon solvent reaction/decomposition products). The difficulty is to make sure that all the hydrazine is removed after the test so that the residual hydrazine does not cause corrosion problems beyond those suspected prior to performing the test.

Hydrazine vapor inhibited the rate of crack growth during fatigue testing of pre-cracked Al-7075-T6, an aircraft alloy [1782]. Although the control sample (60% RH air) failed (2-in. crack formation) after only 33000 cycles, the same sample in hydrazine vapor managed to survive 60000 cycles. Crack growth seems to be accelerated by moisture. If the control test was conducted in dry air, it failed after 44250 cycles.

## 5.6 Hydrazine Compatibility with Non-Metallic Tank Materials

Composite overwrapped pressure vessel (COPV) tanks with a thin metal shell allowed considerable mass savings in spacecraft design. Initially COPV tanks were used only for pressurant gases, but later these tanks were used for both pressurant gases and liquid propellants. If propellant is accidentally spilled on the outside of the tank or it leaks through a pinhole in the shell, the integrity of the composite overwrap may be jeopardized, and the tank may burst [1783, 1784].

## 5.7 Liquid Hydrazine Impingement in Vacuum

Occasionally hydrazine leaks are suspected to have occurred in flight systems, and it was suspected that leaked hydrazine ice and hydrazine vapor may have destroyed adjacent electronic components. Several liquid/frozen hydrazine spray impingement tests and vapor exposure tests under simulated space conditions have been conducted for many materials that would ordinarily not be exposed to hydrazine. The main concern was that hydrazine (vapor, liquid, or frozen) might jeopardize the insulating qualities of electric cable insulations and cause electric shorts.

Other situations where hydrazine impingement is potentially fatal include where it impinges on and dissolves space suits worn by astronauts during extravehicular activity (EVA) and propellant transfer operations in space. Material compatibility tests have been conducted with space suit materials to make sure that the materials are

compatible with a wide range of corrosive propellants [1785, 1786]. When sprayed onto space suits in vacuum, hydrazine will freeze, and it sublimates only slowly [111].

## 6 Selection of System Components for Hydrazine Service

The selection of system components for monopropellant and bipropellant flight propulsion systems is a carefully guarded trade secret with most of the hydrazine propulsion system suppliers. The rationale in selecting compatible system components (valves, filters, tanks) may determine the success or failure of a flight mission. Little useful information can be learned from published reports. In addition, because the availability of components changes so rapidly, recommendations for specific types and models of valves and filters have only limited time value. Some materials may no longer be produced, and new materials are becoming available all the time; the same is true of components made from these materials.

### 6.1 Examples of Component Incompatibility Problems and Propellant Contamination Incidents

Despite extensive laboratory testing with test coupons and efforts to eliminate incompatible materials before including them in hydrazine system assemblies, several instances of compatibility problems on the systems level have unfortunately occurred. The following paragraphs attempt to give a summary of published events to serve as a warning and prevent recurrence of the same problems. There is reason to believe that an equal or even larger number of incidents went unreported and many were swept under the rug, so to speak. However, those hydrazine users who are not willing to learn from the mistakes of the past are condemned to repeat them.

Some of the events listed in the following summary may not necessarily be the cause of incompatible materials but may rather be the result of negligent handling procedures. However, some materials are more forgiving to contamination and corrosion by hydrazine than others. There may be no foolproof material, or it may be prohibitively expensive.

#### 6.1.1 Residual Cleaning Solvents

When degreasing glass capsules with titanium specimens in preparation for hydrazine compatibility tests, Freon-TF (1,1,2-trichloro-1,2,2-trifluoroethane) vapor was inadvertently left in the glass capsules [1787]. The hydrazine turned greenish black and contained 0.78 to 0.99% insoluble black solids (Al and Ti compounds) and 1.1 to 2.9% soluble solids (containing approx. 30% chloride and 8 to 19% carbon). The pressure rise was excessive, and the Ti-6Al-4V coupons appeared mottled where they had been exposed to the liquid. The titanium became so embrittled that the coupons

could be broken by hand. The chloride content of the off-loaded hydrazine NVR was near 30%. This contamination-corrosion mechanism could be reproduced by spiking pure hydrazine with known amounts of Freon-TF and submersing Ti-6Al-4V, Ti, Al, and V in it. It was shown that vanadium reacts with Freon-TF in hydrazine, forming green corrosion products. Corrosion of stainless steel and braze joints in hydrazines is accelerated by residual Freon [1060, 1788].

### 6.1.2 Pressurant Leakage Through Diaphragms

If hydrazine becomes accidentally contaminated with halocarbons (chlorofluorocarbon cleaning fluids, evaporating liquid tank pressurant and lubricants), the corrosion of braze joints and the resulting rate of gas evolution is extremely bad [1711]. Freon-13B1 was at one time used as a pressurant fluid to expel hydrazine from a positive expulsion tank with a stainless-steel diaphragm, but the metal diaphragm may have leaked, resulting in contamination of the hydrazine. Trace amounts of bromotrifluoromethane (Freon-13B1) had been found in hydrazine in a metal diaphragm tank that was pressurized by the evaporating liquid. The metal diaphragm leaked pressurant gas into the hydrazine propellant. The compatibility of hydrazine containing various amounts of Freon-13B1 and Freon-TF with 304L and 308 stainless steels that had been joined with Au-Ni braze and Cu braze was investigated in detail. The results were presented in various tables and graphs. 304L stainless steel and Au-Ni braze were the most compatible of the combinations of materials, and Freon-TF was a more deleterious contaminant in hydrazine than Freon-13B1.

### 6.1.3 Valve Leakage

Injector clogging and valve leakage were observed during a vacuum start study of catalytic hydrazine reactors using dry ice (solid carbon dioxide) for temperature conditioning [1789, 1790]. Contaminant crystals collected on a filter were analyzed and found to be a carbazic acid derivative. A white residue was observed after vacuum evaporation of hydrazine from a simulated flight hardware tank. The residue showed an IR spectrum like that of ammonium bicarbonate. It was most likely hydrazinium carbazate formed by reaction of hydrazine with carbon dioxide. Carbon dioxide from the cooling system or ambient air must have found its way into the propellant and caused this problem. In a few instances on INTELSAT III, valves became clogged by corrosion products, brown crystalline salts from atmospheric carbon dioxide interaction, probably caused by a similar problem.

It used to be common practice to “passivate” EPT-10 diaphragms of propellant expulsion tanks in anhydrous hydrazine prior to flight applications and to measure the gas evolution rate as an indication of acceptability of diaphragms, which varied substantially from batch to batch (diaphragm activity index = DAI). However, EPT-10 swelled and absorbed large amounts of hydrazine during this pre-treatment. For a long time, the users were not aware that the hydrazine could not be completely removed by

water flushing. Subsequent exposure of the diaphragms to air (containing 0.03% CO<sub>2</sub>) allowed carbazic acid to form that slowly attacked the zinc oxide filler in the EPT-10 and converted it to a soluble salt. This salt contaminated the next load of hydrazine propellant with dissolved zinc [1727, 1791]. The zinc leached from the diaphragm, dissolved in the hydrazine as carbazate, and deposited as zinc residue on valve seats. The residue caused the valves to leak during preflight engine tests on the ground with flight tanks that had gone through DAI. Coupons cut from diaphragms removed from other post-DAI tanks showed that the post-DAI samples leached more zinc into clean hydrazine during a 51-d soak test than samples that had not gone through DAI. Subsequently, the DAI pre-treatment of EPT-10 was abandoned, and hardly any zinc was subsequently extracted from the diaphragms. In laboratory tests, it was shown that the amount of leachable zinc from new diaphragms was proportional to the added carbazic acid content of carbazic acid solutions in hydrazine [1727].

Hard-seat valves using Kennametal K-96 showed gas leakage if they were not decontaminated promptly after ATP firing. Exposure of hydrazine-wet valve surfaces to air and carbon dioxide allows carbazates to form in and on the valve seat, where they will corrode adjacent metals. In laboratory tests, the interaction of hydrazine, moisture, air, and carbon dioxide on the cobalt-bonded tungsten-carbide hard seat material was reproduced, and crystals of  $\text{N}_2\text{H}_5[\text{Co}(\text{N}_2\text{H}_3\text{COO})_3] \cdot \text{H}_2\text{O}$  formed on the surface of the metal were identified by chemical analysis. The cobalt is preferentially leached from the material, leaving loose tungsten carbide particles behind.

The Hughes INTELSAT IV HE-54 22-N thruster used a Hydraulic Research dual-seat torque tube valve with tungsten carbide seats and poppets [1792]. The valve, like many other hydrazine valves, was reported to be very sensitive to contamination and had to be thoroughly cleansed of any residual hydrazine before it could be exposed to air (and carbon dioxide therein). If the valve still contained residual hydrazine and was exposed to atmospheric carbon dioxide, carbazic acid would attack the metal parts, and the removal of corrosion products was very difficult. Carbazic acid could cause pitting of smoothly polished surfaces, which may erode further in high-speed flow, preventing a reliable and tight metal-to-metal seal.

The flight-ready ATS-F propulsion subsystem was fueled and subjected to a ground propulsion system test in a large vacuum chamber prior to launch, which was very unusual, and a test procedure heavily recommended against by most other organizations [1793]. Unfortunately, it was very difficult to remove all residual hydrazine after the all-up ground test and before actually launching the satellite. Atmospheric interaction with wet valves caused valve corrosion and valve leakage before the satellite could be launched, but the damage was recognized only later [1794]. Reddish deposits were found on the valve seat area of dissected valves removed from the spacecraft. These deposits prevented complete closure of the valve and caused gas leakage and would have caused liquid leakage if they had remained on the prototype flight vehicle. The light tan to deep red deposits were insoluble in hot water or isopropanol but would slowly dissolve in hot hydrazine.

Chloride-containing corrosion products found were attributed to hydrazinolysis of Freon-TF that might have soaked into the Teflon seats during valve manufacture and valve cleaning. Attempts to reproduce the stainless-steel valve corrosion with carbazic-acid-doped hydrazine in the laboratory resulted initially in water-soluble crystals, which hydrolyzed in moist air, converting to rust-brown crusts, and became gradually water-insoluble. The ATS-6 satellite suffered several valve/thruster failures in orbit, which were blamed on alternating exposure of the entire system to hydrazine and air during ground operations prior to launch [1795].

#### **6.1.4 Injector Clogging**

The clogging of capillary feed tubes in injectors in small hydrazine monopropellant thrusters has been an industry-wide problem. The clogging material could be the non-volatile residue that is always found in hydrazine and has most likely been leached from the distillation towers during manufacturing or from the stainless-steel drums during storage and transport. There are few thorough investigations of capillary feed tube clogging, but they are usually not published.

#### **6.1.5 Silica Shedding**

In a number of cases, injector clogging and catalyst bed fouling were caused by silica shedding from AF-E-332 diaphragms in positive expulsion tanks. Sometimes injector clogging and catalyst bed fouling were observed separately but in parallel in the same type of thrusters fed from the same tank, the only difference being the duty cycle at which the thrusters were operating.

Numerous silica leaching/shedding investigations have been conducted with AF-E-332 and its precursor elastomer, EPT-10. These involved ground tests as part of pre-flight development and qualification programs as well as after-the-fact problem investigations in which silica shedding was one of the prime suspect mechanisms contributing to the failure of propulsion sub-systems in satellites in orbit. They included tests where the hydrazine was exposed to AF-E-332 and subsequently passed through monopropellant thrusters to study the clogging potential of leached contaminants.

OTS-2 was launched on May 11, 1978, on a DELTA-3914, and its BOL mass was 865 kg. OTS-2 and subsequent European Communications Satellites (ECS-1 through ECS-5 = EUTELSAT1 F1 through F5) using similar AF-E-332 diaphragm tanks have all experienced erratic steady-state thrust performance that could not be explained by bubbles entrapped in the feed line [1796]. ERNO replicated the OTS-2 on-orbit behavior in tests on the ground using duplicate flight hardware including tank, lines, valves, and thrusters. This test was often referred to as the ECS long-term test (LTT). Testing was done with 313 K (40 °C) fuel and extended over 1 year. The 0.5-N REA had a capillary feed tube injector. Tests had shown that the OTS-2 problem is a poisoning (fouling, coating of active sites with an inert, unreactive layer) of the catalyst, not injector tube clogging as occasionally observed with long-life gas generator feed tubes

in electrothermal thrusters. For the ground test, 27.5 kg of high-purity-grade hydrazine was loaded and during the third test sequence after 9 months, 23 kg propellant consumption, and less than 30 h cumulative run time, the thruster washed out, as evidenced by solid hydrazine emerging from the nozzle in a vacuum chamber environment. Post-test cold gas flow of the thruster was 22% below nominal, indicating some clogging. Disassembly showed the clogging to be in the catalyst bed and not in the feed tube. The catalyst granules were coated with a glassy layer, which was rich in silicon, as shown by SEM-EDAX. Later testing with two different grades of hydrazine showed that the silica leaching occurred with both grades of hydrazine. The 0.5-N thruster suffered major performance degradation after passing 18–21 kg of propellant, and the 2-N thruster degraded after 25 kg of propellant [1797]. The engineering analysis, partially based on an analysis of telemetry data from satellites still operating in orbit, indicated that 28 to 31 mg of silica deposited in the catalyst bed or on the injector screens of thrusters on board ECS-1, ECS-2, or TELECOM-1A was sufficient to cause thrust degradation. The initial interpretation by European investigators was that the silica came from a mold release powder that was allegedly used in the manufacturing of the diaphragms, not from the diaphragm rubber itself. This representation was disputed by tank manufacturers. The OTS and ECS diaphragms with cylindrical midsections were manufactured in the mid-1970s, and the manufacturing methods may have changed since.

The EURECA retrievable carrier platform did not experience any thrust decay problems while in orbit but is a valuable data point in assessing the rate of silica leaching from diaphragms. It offered a rare opportunity to inspect a satellite propulsion sub-system after it had flown in space for almost 1 year. EURECA-1 was launched on STS-46 and retrieved by STS-57 after 10 months in orbit. It had thrusters of three different thrust levels, including 2-N, 5-N, and 20-N REAs with shower head-type injectors. It carried 660 kg hydrazine in six tanks of equal size, enough to maintain orbital elements for twice the intended 9- to 10-month mission duration, and close to the nominal maximum full load of 670 kg liquid propellant. After its retrieval, EURECA-1 offered a unique opportunity to physically “hands-on” examine thrusters that had actually operated in space and were fed from tanks with AF-E-332 diaphragms. There are thousands of thrusters like them in orbit, but they are usually inaccessible for post-flight examination. EURECA-1 thrusters that have flown once were initially earmarked for another EURECA flight (EURECA-2) and were not available for D&I. The reflight opportunity was canceled, and the fate of the thrusters remains unknown. Apparently only one of the thrusters was taken off the platform and ATP test fired on the ground, providing performance identical to its first ATP. The thruster was then reinstalled on the platform and was destined to fly again until the reflight was canceled.

Hydrazine off-loaded from EURECA-1 following the flight had a silicon content identical to that found in a similar tank during ground testing. The propellant had spent 450 d in the tanks. The results are summarized in Table 71.

**Table 71:** Summary of silicon analysis in hydrazine off-loaded from EURECA-1.

| Tank No. | Residual propellant, L | Silicon concentration, mg Si/L | Mean surface: volume ratio | Silicon generation rate, ng Si cm <sup>-2</sup> d <sup>-1</sup> |
|----------|------------------------|--------------------------------|----------------------------|-----------------------------------------------------------------|
| 1        | 56                     | 0.44                           | 0.0647                     | 15.1                                                            |
| 2        | 80.7                   | 0.42                           | 0.0581                     | 16.1                                                            |
| 3        | 110.3                  | 0.38                           | 0.0551                     | 15.3                                                            |

Data source: [1798]

As one can see from Table 71, the silicon concentration in all tanks was substantially (by one order of magnitude) above the maximum silicon concentration tolerated for electrothermal hydrazine thruster testing. ESA assumed an average silicon generation rate of 12 ng Si cm<sup>-2</sup> d<sup>-1</sup>. This is below the rate reported by ERNO in earlier OTS/ECS LTT tests. The lower numbers during the first months of leaching in hydrazine may be due to the system-level checkout of the entire flight system on the ground prior to launch using water as an inert hydrazine simulant [1798]. Some silica may already have leached into the water. The off-loaded water was not analyzed for colloidal SiO<sub>2</sub>.

If one plots the amount of silicon found in the off-loaded propellant versus the mean surface: volume ratio, it appears that there is an almost linear, very steep relationship for tanks 1 through 4. However, tanks 5 and 6, which were emptied early in the mission, do not fit this relationship. Tanks 1 through 4 were emptied late in the mission. This would indicate that much of the silica was shed early in the exposure sequence, and the high *A/V* ratio for the remainder of the mission has not resulted in higher silicon concentrations. ESA calculated the maximum amount of hydrazine passed through a single 20-N thruster during the EURECA-A mission and concluded that the maximum consumption of a single thruster was 92 kg, which is substantially less than the 175 kg/thruster for which the system was qualified. Therefore, they concluded that the thrusters returned from space are good for another mission.

It would be of interest to obtain hydrazine analysis results from the Japanese Space Flier Unit, which was also retrieved by the Space Shuttle and returned to Earth. It is not known what type of tank was installed on this reusable spacecraft. If it was an AF-E-332 tank, the hydrazine should be subjected to a thorough analysis for leached contaminants. Likewise, if the thrusters are not needed for another mission, they should also be examined for contaminant deposition.

Matra Marconi Aerospace conducted ground tests with the ERNO 5-N and 20-N thrusters qualified for EURECA and intended for SOHO with propellant taken from a tank that contained an AF-E-332 diaphragm like the flight unit [1799, 1800]. They found that silica deposition occurred predominantly in the injector area, not in the

catalyst as with the smaller 0.5- and 2-N thrusters. Silica deposition in the catalyst bed was measurable but did not disable the thruster. It was concentrated axially in the core of the catalyst bed. MATRA developed a mathematical model to predict silica concentrations in hydrazine as a function of surface: volume ratio, time, and temperature. Another opportunity to examine hydrazine tanks and thrusters returned from space would have been with the Atmospheric Reentry Demonstrator, although the wetted time was only relatively short.

There are several postulated mechanisms for thruster degradation by silica deposition:

1. High-pulse-number missions where the injector holdup volume/dribble volume vaporizes after each pulse, leaving a layer of NVR, often uniformly distributed over the entire length of the capillary injector tube;
2. Long steady-state firings with lots of heat soak-back, where thermal margin is lost and film boiling starts at a point somewhere between the valve outlet and the injector face, depending on heat conductance and presence or absence of thermal shunts;
3. Gross catalyst coating with NVR deposits and fouling of the catalyst bed;
4. Platinum screens form a low-melting alloy with silicon and degrade prematurely.

In the case of catalyst coating (item 3), silica in the presence of other metal oxides, in particular sodium oxide, forms low-melting glasses that wick into the catalyst pore structure and effectively seal it off from hydrazine flow. Pure  $\text{SiO}_2$  melts at temperatures above thruster operating temperatures and deposits appeared to be coalesced like glass, but one should not expect the deposit to be pure  $\text{SiO}_2$ . Any other oxide, predominantly sodium oxide, will lower the melting point and form a glass.

In addition to the concern about injector clogging and catalyst fouling, there is concern about elemental silicon (formed by reduction of silica by hot hydrazine) in contact with platinum (item 4 above). Some injectors use platinum or rhodium/platinum screens as dispersion elements. In the presence of very small percentages (% by weight = equivalent to larger percent by atom population) of silicon, the melting point of platinum is lowered to below the operating temperature of a hydrazine reactor and the screens fail. There is some silica already in the alumina from which Shell 405 is made, but additional silicon carried in with the propellant or diffused from adjacent L-605 alloy makes things worse. Platinum/rhodium screens appear to be less susceptible to silicon damage than pure platinum screens.

Many questions remain open as to the nature of the silicon-containing compound leached from AF-E-332. It could be a physical suspension or a chemical solution. Depending on the particle size, a physical suspension should make it possible to filter out the silica particles. Silica cannot be filtered out mechanically. It is either colloidal or it is in dissolved form. Propellant sampling for particulate matter becomes very difficult because the tanks should be agitated and stirred each time before taking a sample. Otherwise it would be impossible to obtain reproducible particulate results, and one

is more likely to obtain high readings toward the end of the test when the “dredges” remaining in the tank bottom are used up.

The silicon problem was not evident with EPT-10, which used Silene-D silica that was not made hydrophobic. Some investigators maintain the position that silica leaching was overshadowed by problems with zinc leaching with this precursor polymer. Also, engine lifetimes and mission durations in the days of EPT-10 were short in comparison to the 10- to 15-year useful life requirements of today’s satellites. EPT-10 contains 65 parts  $\text{SiO}_2$  per 100 parts polymer, whereas AF-E-332 contains only 30 parts  $\text{SiO}_2$  per 100 parts polymer. AF-E-332 contains less  $\text{SiO}_2$  but, oddly enough, has a worse  $\text{SiO}_2$  shedding problem. There must be some contributing factor other than the gross  $\text{SiO}_2$  concentration in the rubber. One of the differences is that Silene-D was not made hydrophobic by silane treatment. Free hydroxyl (silanol) groups in Aerosil R-972 are converted to dimethylsilylether linkages by reaction with dimethyldichlorosilane. Approximately 70% of all silanol groups are converted by reaction with the dimethylsilane, resulting in the disappearance of the —OH stretching bond in the IR spectrum of the material. Hydrazine can hydrazinolyze the ether/ester linkages and form silylhydrazines, which are totally soluble in hydrazine, but would decompose under injector and reactor conditions to  $\text{SiO}_2$ .

Two flight tanks were tested side by side for storability and contaminant leaching [1761]. One tank was a CTS tank with an EPT-10 diaphragm made by PSI; the other was a Block 5D tank with AF-E-332 made by TRW. The testing covered the period from 1974 to 1985 for a total of 11 years. In the EPT-10 tank, silicon (silica?) ranged from <0.6 to <3.3 ppm with a final value of <1 ppm, whereas in the AF-E-332 tank, silicon content ranged from <1.5 to 15.5 ppm with a final value of 10.9 ppm Si. Despite the high silicon level, investigators concluded that this is *not considered sufficient to cause deterioration of the bladder or pose a potential valve leakage problem*. They did not address feed tube clogging or catalyst fouling. They also test fired 0.2-lb<sub>f</sub> thrusters with hydrazine off-loaded from tanks in which AF-E-332 had been soaked and did not observe any untoward effects. Hydrazine that was stored in contact with AF-E-332 for 200 d at 344 K (160 °F) and later used for engine tests showed a significant increase in silicon content (up to 45 ppm) [1801]. Elastomer EPT-10 was also tested in the same series, as well as in a GPS flight tank for 5 years. The silicon increase in EPT-10 diaphragms was only moderate (from less than 1.5 to 2.25 ppm). The zinc content in hydrazine exposed to EPT-10 remained low because the carbon dioxide content was also carefully controlled, and the hydrazine-soaked diaphragm was never exposed to ambient air. The exposed hydrazine was analyzed not only for silicon and zinc, but also for seven other metals and eight other constituents. After the test sequence with contaminated fuel, the thruster had accumulated 22348 pulses, whereas an ordinary GPS mission at that time required only 1000 pulses. Even with contamination that far exceeds MIL-SPEC limits, the thruster was expected to deliver the total impulse as under normal conditions.

In a tank qualification test program for FLTSATCOM, most of this effort was concerned with mechanical properties and expulsion efficiency [1765]. A propellant sample collected from the tank after 31 weeks contained 1.92 ppm Si, and a control kept in a glass bottle had 0.64 ppm Si. The difference was less than the stated accuracy of the analysis method used. A mission life test with the MRE-0.2 lb<sub>f</sub> thruster was conducted with propellant supplied directly from a flight tank containing an AF-E-332 diaphragm after 6 months' storage at 344 K (160 °F) [674]. Post-test performance compared favorably with identical tests on other thrusters fired from facility tankage, indicating no measurable effects of the AF-E-332 diaphragm on thruster operation.

When normalizing the results obtained at different organizations by the surface:volume ratio and correcting for temperature, consistent silica concentrations were obtained per unit area. The silicon content was normalized to  $A/V = 0.05 \text{ cm}^{-1}$  and 297 K (75 °F). However, correlation as a function of immersion time was not good [1061, 1764].

Another comparison of leaching study results also included data on Dowty D11, a European replacement material for AF-E-332. Its silica shedding rate was worse than that of AF-E-332. The rate entered for EURECA-A was close to  $12 \text{ ng cm}^{-2} \text{ d}^{-1}$ , and it is assumed that this is silica, not silicon. Some reports are not specific if the reported numbers are silica (molecular weight 60.8) or silicon (atomic weight 28.09). In summary, after several silica-induced problems were published, the rocket propulsion industry is now generally aware of the limitations of current technology elastomer materials, and corrective action has been taken by both the suppliers and the end-users.

### 6.1.6 Other Material Compatibility Problems in Components

In some rare instances, materials became corroded when hydrazine leaked onto external parts in the presence of air and moisture. This problem is caused primarily by the external leakage (which was not supposed to happen), but if the leakage cannot be prevented, one may need to rethink the materials selection and include an answer to the "What if ...?" question. In the case of the gear drive for a hydrazine fuel pump (which is on the same shaft as the turbine lubricant pump), which was made from M-2 tool steel, the primary selection criterion was the hardness of the material. M-2, in particular rusted M-2, is more reactive toward hydrazine than any other metals once found in the STS APU. Rusted M-2 can initiate an exothermic reaction at 335 K (62 °C). Unfortunately, the graphite ring bearing in the fuel pump does not provide a perfect seal (it shrinks when it dries out), and hydrazine was often found in the fuel drain cavity (now separated from the lubricant drain cavity). Hydrazine in the fuel drain cavity was a potential hazard if it ignited on the M-2 tool steel dust. The NHB 1060.1c Test 15, ARC, and a thermal runaway temperature (TRT) test, like the liquid-phase exothermicity test (LPET), were used to determine the potential ignition hazard [1802]. It was concluded that oxygen should be excluded from the fuel drain cavity to lower the risk of ignition. Coating the gear with Apiezon-L provided only limited protection.

## 6.2 Cleaning and Passivation Methods

Because hydrazine is so sensitive to contaminants introduced with a freshly forged, welded, spun, drawn, or machined surface, cleaning and passivating methods have been recommended prior to filling a propellant tank with hydrazine and launching a spacecraft. These methods are applicable mainly to anhydrous hydrazine. There seem to be fewer corrosion and compatibility problems with flight systems using methylhydrazines as bipropellant fuels.

### 6.2.1 Cleaning Methods

The cleaning methods for stainless steel, aluminum, or titanium alloys are usually very well established in the industry. The objective is to remove oxide coatings left over from extruding, deep drawing, or spinning the metals while in the hot state. Welded specimens must be cleaned to remove weld fluxes, weld spatter, and oxide layers. Removal of greasy contaminants from cutting fluids or lubricants used during the machining process is usually done with organic solvents. CFC-113 (Freon-TF) was widely used on the parts level until it was banned for environmental reasons along with other ozone-depleting chlorofluorocarbons. Trichloroethane (methylchloroform) and trichloroethylene were also widely used at one point. The problem is that if these halogenated solvents are not completely removed from the assembled units, subsequent aggravated corrosion in hydrazine may lead to system failures. All components for a  $\text{ClF}_5/\text{N}_2\text{H}_4$  rocket engine test stand were meticulously cleaned using a method that avoided the use of chlorofluorocarbon cleaning solvents [1803].

#### 6.2.1.1 Contamination Incidents with 2-Propanol

Isopropyl alcohol (IPA) (isopropanol, 2-propanol) is usually used for removing other organic contaminants, and sometimes it is used to replace and flush out water from complete flight systems following spin tests, center-of-gravity determinations, or acoustic tests with water in the propellant tanks simulating the actual propellant. IPA is easier to remove from a system by hot nitrogen purge and/or evacuation than water. IPA is compatible with most materials that hydrazine is also compatible with and it is miscible over the entire range of mixture ratios with water and/or hydrazine. The only problem with IPA is that it may contain up to several percent acetone as a result of selecting a crude solvent grade to start with or as a result of inadvertent autoxidation of high-purity IPA during storage in partially filled drums when a nitrogen blanket is not maintained. The procurement specification for IPA for hydrazine service should limit the amount of acetone tolerated. Residual IPA in a flight system will become partially autoxidized to acetone while the fuel system is sitting idle waiting for fueling. If acetone-containing IPA residues in the system mix with hydrazine, a brown polymeric mass ("mess") of hydrazones/azines forms that may clog filter screens and cannot be removed by either IPA or water. This was the cause of a satellite propellant loading ground-service cart contamination incident.

The only solvent that will remove the brown goo is hydrazine. Hydrazine is the best known solvent for cleaning out brown polymeric residue.

A fuel cart intended for ATS-F had to be totally disassembled and rebuilt after it became clogged from reaction products of bad IPA and hydrazine. A propellant loading cart built by another contractor in 1972 experienced similar contamination problems. There have been several incidents where the hydrazine loaded from a drum into the propellant cart was perfectly clean, but the propellant cart contaminated the hydrazine, in particular when it was used for the first time or if it was left unattended and partially filled between launches.

IPA may ignite on iridium catalysts in air and its oxidation products may poison the catalyst. It is not recommended to flush IPA through monopropellant thrusters intended for flight use, although this had been done at some locations, apparently without undue effects. It should be mentioned that IPA in prolonged contact with air may form explosive peroxides that are likely to explode when attempting to distill aged and recycled IPA for purification.

#### **6.2.1.2 Contamination Incidents with Alkaline Cleaners**

In an effort to use more environmentally friendly cleaning methods, avoiding all halogenated solvents, water-based cleaning agents are now widely adopted as substitutes. This is not without problems, as illustrated by the Space Shuttle boosters where SRB motor liners did not bond properly after the manufacturer had switched to a so-called “green” cleaning agent, delaying the return of a frustrated lady astronaut from Mir in 1996.

One of the water-based cleaning agents used to clean CRES-304L tubing is Turco 3878, which contains diethylene glycol butyl ether, detergents, silicates, and hydroxides. If it is used in excessive concentration and with insufficient water rinse, the glass-hard silicate residues formed after drying or on contact with hydrazine will be impossible to remove with chemical solvents.

#### **6.2.1.3 Contamination Incidents with Halogenated Solvents**

Residual Freon solvent in a propellant system causes hydrazine or MMH to become more corrosive, attacking the titanium [1787] or stainless-steel screen [1060, 1804] in the PMD in surface tension tanks. All hydrazine users should examine the assembly/servicing procedures and make sure that Freon-TF or other halogenated solvents are no longer used. Trichloroethane (methyl chloroform) or trichloroethylene causes similar problems. Sometimes halogenated solvents have been used to clean only a pressurant gas system, which ordinarily would never be exposed to hydrazine, but pressurant gas carried residual solvent vapors into the propellant tank, where it reacted with MMH. In reproducing the problem in the laboratory, MMH was doped with 0.25 to 2.5% Freon-TF, and 96Sn/4Ag solder, Ti-6Al-4V, iridized aluminum 6061-T6, and stainless-steel samples were immersed in the adulterated propellant for 63 d [1060, 1804]. Freon is less soluble in hydrazine than in MMH. In similar tests

with hydrazine, initial Freon solubility was limited to 0.5%. Yellow discoloration of the propellant was usually observed within a few days. The iron concentration leached from CRES increased to several hundred ppm. In tests where hydrazine was doped with fluoride, it was shown that hydrogen fluoride doping accelerated the corrosion of metals (except aluminum) so that the corrosion and blackening of the samples were evident within hours, but potassium fluoride addition did not corrode the metals. It is thus the hydrazinium  $[\text{N}_2\text{H}_5^+]$  cation in the presence of fluoride or chloride that is the corroding agent. The halide ion may aid in complexing metal ions once the metal is dissolved, for instance by forming  $[\text{FeF}_6]^{4-}$  complex ions. An electrochemical method was used to analyze trace fluoride in hydrazine [1804].

There was a problem when the decomposition of residual Freon-TF vapors, most likely present during the brazing of pressure transducers, caused subsequent rust formation on the 15-5PH metal braze stub of an unused pressure transducer while it was sitting in a plastic bag in ambient air on a shelf. The rust would constitute a potential problem for an identical pressure transducer that was already installed in a kick stage being readied for launch at the time the rust was discovered in its unused twin. In a laboratory test in glassware, it was shown that gas evolution from the rusted part immersed in hydrazine was much faster than from a clean braze stub of the same metal undergoing a parallel test for comparison. Despite the faster gas evolution from the rusted part, the projected overall gas evolution and pressure increase in the blowdown tank was not significant enough to warrant a “last-minute” recall of the kick stage for a space probe a few weeks prior to launch. This was confirmed by measuring the tank pressure for several weeks after loading the propellant and just prior to launch.

Liquid Freon-13B1 was used as a pressurant gas in a hydrazine expulsion system with metal bellows. Since the evaporation of Freon maintains a constant (although temperature-dependent) feed pressure (near 1300 kPa = 190 psi), this results in more reproducible rocket engine thrust than blowdown from a compressed gas source without a regulator. Unfortunately, metal bellows can be cycled only one to five times. Elastomer (AF-E-332) bladders or diaphragms would be superior to metal bellows since they can be cycled many times. However, Freon permeability through rubber prevents direct replacement of metal bellows with elastomer bladders [1805].

#### 6.2.1.4 Reactivity with Cleaning Agents

The reactivities of several selected halogenated precision cleaning solvents with hypergolic propellants was determined by analysis of the rates of formation of halide ion decomposition products [1806]. The solvents tested were Asahiklin AK 225, Asahiklin AK 225 AES, HFE 7100, HFE 7100 DE, Vertrel XF, Vertrel MCA, Vertrel MCA, Plus, 1,1,2-trichloro-1,2,2-trifluoroethane (CFC-113), and trans-1,2-dichloroethylene (DCE). The propellants tested were hydrazine, MMH, and mixed oxides of nitrogen (MON-3). The Vertrel solvents showed significant reactivity with hydrazine. All the solvents except DCE exhibited significant reactivity with MMH, particularly HFE 7100 DE and CFC-113.

### 6.2.2 Passivating Methods

Some investigators recommend passivating fuel tanks and lines by filling the system with full-strength hydrazine, allowing the system to sit idle for some time, off-loading, and refueling with fresh fuel immediately prior to flight. Other schools of thought recommend keeping the entire system dry until fueling immediately prior to launch. This approach is frequently dictated by the fact that it is very difficult if not impossible to decontaminate a system of residual hydrazine between the passivation exercise and the actual launch.

A wide variety of passivation procedures are practiced by contractors working on hydrazine systems, but no standard technique has emerged. The basic process generally includes wetting all critical internal surfaces with hydrazine or hydrazine/water mixtures. In some cases, a dilute hydrazine solution is used first, followed by anhydrous hydrazine. Some procedures recommend heating the system to accelerate the passivation process. The passivating fluids are left in the system for 2–48 h and then discarded. Success criteria are not always applied to gauge the results of the treatment. In some cases, the rate of pressure buildup during passivation is monitored, or a particle count is taken on the off-loaded fluids. In a survey of the propulsion industry in the 1970s, it was noted that there was a “wide diversity of procedures, all somewhat lacking in credibility,” and there was “no basic agreement about necessity or value of conditioning at all” [1659, 1660]. When attempts were made to establish a correlation between pressure rise rates observed on freshly fueled all-up systems and gas evolution rates obtained in the laboratory on individual components, rates of gas evolution at 322 K (120 °F) were measured on CRES-301, CRES-304L, CRES-308L, and a 82Au/18Ni braze alloy in addition to Al-2021 and Ti-6Al-4V. It took more than 800 h for the gas evolution rate to level off, a sign of removal of the initial consumable layer on stainless steels. Calculations assuming additive contributions from each wetted component for a system at a fill rate of 60% (40% ullage) agreed only moderately well with the measured pressure rise rate during the pre-launch hold period.

Tanks (37.6 L = 10 gal volume) made of stainless steels (A-286, AM-350, and 17-7PH) and Ti-6Al-4V were passivated by the manufacturer with a mixture of 40% hydrazine and 60% water for 24 h at 361 K (190 °F) [1807]. Stainless-steel tanks showed a distinct pressure rise during passivation, but titanium tanks did not. Aluminum tanks were passivated with MIL-SPEC-grade anhydrous hydrazine for 24 h at 325 K (125 °F).

Only a few investigators reporting the results of material compatibility tests with hydrazines disclose the cleaning and passivation techniques used during their study to prepare metal coupons for tests. References [1638] and [1647] are an exception because they are some of the few that listed the cleaning and passivation to which coupons were subjected prior to immersion in hydrazine.

Sometimes flight tanks or entire flight systems are filled with hydrazine, and pressure rise is observed during the pre-launch hold period to see whether any inadvertently introduced, catalytically acting contaminants cause a higher than normal pressure rise rate. For instance, the complete propulsion sub-system on Intelsat IV was

vacuum filled to capacity with anhydrous hydrazine and connected to a small ullage volume (approx. 160 mL = 10 cu. in.) and heated to 350 K (170 °F) [1808]. After temperature stabilization, the system's pressure was monitored for 24 h.

## 6.3 Flow Controls for Hydrazine Systems

Precision impulse bits delivered from hydrazine propulsion systems depend on accurate metering of the hydrazine flow to the thrusters. A wide variety of hydrazine flow control components are on the market and the list of available components changes daily.

### 6.3.1 Solenoid and Torque Motor Valves

Valves are the most important components in hydrazine monopropellant flight systems, and the selection of the correct valve is a science in its own right. The marketplace of valve suppliers is changing frequently and requires constant attention by a component engineer. Many space flight missions have been cut short by valve failures. Failure modes can be a failure to open, failure to close, or slow leakage in the closed position. Leakage can be internal leakage or external leakage. The word *valve* will likely evoke an immediate association with valve leakage. One of the more dramatic bipropellant valve failures occurred on GEMINI 8 when bipropellant roll control thruster valves got stuck open and accelerated the space capsule to a whirlwind roll. Shortly after the GEMINI and the AGENA docked, the craft began spinning out of control. Armstrong jettisoned the AGENA, thinking the problem was there, but the tumbling worsened. Armstrong shut down the GEMINI's reaction control system and manually brought the craft under control using a second set of 16 thrusters intended only for use on re-entry during a later phase of the mission.

The discussion here is restricted to valve materials and does not extend to valve designs. Several publications discussing hydrazine thruster designs will often also provide useful information on valves. For instance, sometimes the only difference between a manufacturer's thruster model designation like HE-54 or HE-55 is the valve. The most sensitive part of a valve is the sealing surface, the point of contact between the seat and the poppet. We differentiate between soft seat valves and hard seat valves.

Hydrazine is a very poor lubricant, and metal-on-metal sliding fit valves are susceptible to damage of the sealing surface even when operating in the wet state. Basic data were acquired on the sliding characteristics of metal surfaces under hydrazine to gain an understanding of the phenomena of wear and friction inside these valves [1809]. Sliding fit valves should never be operated in the dry state.

Measurements in a friction tribometer that simulates the sliding parts in thruster valves showed that the tribological properties heavily depend on the lubricating ability of the applicable fluid. Hydrazine is a very poor lubricant. In the case of hydrazine,

the typical phenomena were galling due to the strong reducing property and chemical change of the sliding surface [1810].

#### 6.3.1.1 Materials of Construction for Solenoid Valves

A wide range of valve materials was surveyed as part of the advanced valve technology program [1637]. The survey included 15 aluminum alloys, 14 steels, 18 miscellaneous metals, and 15 non-metals.

Valve seat (AF-E-411 and AF-E-102), armature (CRES-430 and CRES-430F), spring (CRES-302 and 17-7PH), and housing samples (CRES-304L, CRES-347) representative of the MJS77 (VOYAGER) systems were tested in JPL long-term storage tests [1160, 1638].

One of the most important and most complex components of the Space Shuttle APU was the gas generator valve module (GGVM), which was a block containing several valves. Until the late 1990s, it used a hard seat (tungsten carbide/Co seat, tungsten carbide/Co poppet) and was qualified for 450000 operating cycles. During each typical Space Shuttle orbiter mission (start *and* landing), the valve would have to cycle 6300–7500 times to control flow of hydrazine to the gas generator and control the spin rate of the turbine wheel and the hydraulic fluid pump delivering hydraulic fluid to the main engine swivel actuators, rudders, and elevons, as well as to the landing gear and air brake during landing. A similar but different valve was used on the solid rocket booster hydraulic power units. The metal-to-metal seal on the orbiter was very susceptible to particulate contamination and corrosion at the hydrazine-air interface. Slow leakage during idle periods would cause corrosion of injector stems and injector panels, partially through hydrazine and ammonia that became oxidized to nitrate ion on the Shell 405 catalyst in the presence of traces of oxygen. It would be difficult to replace the metal-to-metal seal by a metal-to-elastomer seal because this part of the system gets very hot despite thermal shunts and (occasionally) active water spray cooling. In an effort to replace the metal-to-metal seal, NASA initiated a program to evaluate other valve seat materials and sponsored development and testing of a new GGVM [1811]. The operating pressure at the valve inlet was 11 MPa (1600 psi), requiring an extra-rigid construction of the housing and connectors. The corrosive chemistry environment at the outlet region of the valve made it more difficult to select alternative materials. Most valves used for hydrazine in satellites are welded constructions and cannot be opened without destroying the valve. Design constraints for the Space Shuttle included a non-welded fluid mechanical portion of the valve to permit disassembly and refurbishment of the valve module as required. Spring-cushioned seat designs were employed to reduce peak impact loads on the sealing surfaces during valve operation to achieve the high cycle life performance required while maintaining acceptable leakage performance. The spring-supported seats not only cushioned the dynamic impact during valve operation but also provided a degree of angular compliance, which facilitated the matching of the sealing surfaces between the valve poppet and the seat. Flat-faced metal-to-metal sealing surfaces have been shown to provide adequate sealing performance for three of the four seats, while PTFE against metal

has performed successfully for the one seat that has the zero liquid leakage sealing requirement but a relatively low 60000 cycle life capability.

#### **6.3.1.2 Valve Failure Investigations**

Thermal management of temperature in spacecraft hydrazine valves and lines is critical. Quite frequently valves and lines have heaters attached to keep the hydrazine from freezing. In at least one case, hydrazine freezing in a valve has caused loss of a satellite [1812]. In another instance, Kel-F valve stem packings in a fill valve disintegrated during six sterilization cycles at 408 K (275 °F), allowing much of the pressurized hydrazine to leak out [1813].

One of the most thorough valve leakage investigations was the one conducted on ATS-F [1794]. It illustrates the wide range of tools available to the component engineer to examine valves that are not operating properly and to determine the cause of the problem. The cause of the problem was incomplete removal of hydrazine from a flight unit following a ground test where it was filled with hydrazine and test fired in a vacuum chamber several months before it was launched into space. None of the satellites launched later was subjected to complete propulsion sub-system hot fire testing in a vacuum chamber on the ground prior to launch.

During early Space Shuttle flights, a few GGVMs suffered leakage and limited life due to wear and breakage of the tungsten carbide valve seat [1744]. Considerable effort was invested in redesign of the seat and in improving manufacturing techniques. This resulted in a seat design with concentric, dual-sealing surfaces and re-designed internal flow passages. The seat was honed with a diamond paste to remove a re-cast layer left after EDM machining. The re-cast layer was the cause of stress risers and seat cracking. It was learned that the tungsten carbide/cobalt material was sensitive to many solvents. Leaching of the cobalt binder can significantly reduce strength. Stress concentrations were avoided by rounding corners. Eventually, the valve armature on the coil side of the flex tube was filled with damping oil to reduce impact speed and valve chatter (rebound).

#### **6.3.1.3 Ground Service Equipment Valves**

On September 30, 2005, at WSTF TC 844B during a low-pressure test, a 0.5-in. manual valve bonnet (B-nut) failed catastrophically under a moderate pressure of only 345 kPa (50 psia). The failure caused the valve bonnet and stem to be ejected from the assembly, thus spilling approximately 74 gal of liquid  $N_2H_4$  into the test cell [1814]. The failure began as an intergranular crack in the nickel-plated, aluminum bronze bonnet threads. It was believed that the crack began as a result of the ethylene propylene rubber and Teflon soft seals allowing corrosive agents to slowly leak into the thread region where they reacted with  $CO_2$  in the air. Contributing causes of the bonnet failure were that material compatibility for non-wetted components was not considered during valve procurement, and the bonnet may have been overtightened (excessive torque when assembling) [1815].

#### 6.3.1.4 Correlation between Gas and Liquid Leakage

The objectives of a hydrazine valve leakage evaluation program were to demonstrate simple, reliable measurement techniques for valve seat leakage, to investigate pressure, temperature, and cycling effects on valve seat leakage, and to establish a correlation between liquid hydrazine leakage and gaseous nitrogen leakage [1740]. The results indicated that, whereas gas leakage is a strong function of inlet pressure, liquid hydrazine leakage is not strongly affected by inlet pressure. The amount of leakage is inversely proportional to the temperature (probably a viscosity function). Two satellite thruster valves were tested for leakage at temperatures up to 394 K (250 °F). Attempts to correlate hydrazine and nitrogen leakage were hindered by the significant liquid leakage variation with time, that is, random leakage variations with each valve actuation. In some cases, liquid hydrazine leakage will decrease with valve exposure time to propellant. This could be caused by particles in the hydrazine that become trapped in the leaking passage and clog some of the paths entirely. Swelling of soft valve seat elastomers with continuing hydrazine immersion has often been ignored and was not too well characterized.

Attempts have been made to establish a correlation between liquid hydrazine and gaseous nitrogen leakage rates of solenoid latching valves [1160]. It was shown that AF-E-411 swelled in the presence of liquid hydrazine, IPA, or water, and then contracted again in the dry state. There is some hysteresis such that the elastomer may not return to its original dimensions after a swelling/drying cycle. Valves that flow correctly during short-term exposure to hydrazine (as during an ATP firing) may not flow correctly after extended soaking in hydrazine because the valve seat has swollen and the clearance between the poppet seal and the seat in the valve open condition has diminished. Less clearance allows less propellant flow.

Six normally closed thrust chamber valves and two latching solenoid valves were tested for hydrazine service simulating a deep-space mission (VOYAGER-Jupiter-Saturn) including 100000 cycles [1739]. Valves included hard seat (metal-metal) and soft seat (metal-elastomer) valves. One case of gross material incompatibility was observed where a soft seat valve seat made from EPR (Parker Compound EPR E-515-8) swelled so badly as to prevent any flow through the valve when the armature was actuated. Other materials tested in valve seats included Teflon, AF-E-102, and tungsten carbide. It is sometimes difficult to correlate gas leakage measured on the dry valve prior to a test and the liquid hydrazine leakage during the test.

Valve leakage can be measured by enclosing and pressurizing a volume of hydrazine upstream of the valve seat. A flexible membrane forms part of a chamber holding a volume of hydrazine. Hydrazine leaking away causes a deformation of this membrane that can be measured [1816]. Special care must be exercised to remove all gas bubbles before loading the hydrazine to achieve maximum system hardness. The compressibility of hydrazine must be known for data reduction.

#### 6.3.1.5 Special Valve Applications

The Strategic Defense Initiative of the 1980s posed a previous unmatched challenge to the missile designer: The entire kinetic kill vehicle was to weigh only 2 kg, including IR seeker, control electronics, battery pack, attitude control thrusters, divert propulsion thrusters, propellant, and propellant tanks and feed system. This challenge resumed at the turn of the millennium with work continuing on a US national missile defense system. In pushing miniaturization to an extreme, coaxial monopropellant solenoid valves as light as 6 g were developed and tested [1817]. Cold gas thrusters weighed only 2.3 g. Warm gas thrusters providing 90 N thrust and operating on hot hydrazine decomposition products from a plenum weighed only 22 g. A miniature pilot-operated valve for divert engines was designed and developed in response to the need for high-flow capacity valves that exhibit the fast response times and weights typically associated with valves providing much lower flow rates [1818]. Hard seat valves with metal-to-metal seals are capable of withstanding higher operating temperatures, as well as in bipropellant thrusters, but are more susceptible to leakage than soft seat valves [1819].

Valves for small thrusters used in missile post boost propulsion systems must satisfy long-term storage requirements, but valves intended for the upper stages of satellite launchers or satellites are usually flown soon after they are installed in the propulsion sub-system. Very rarely is there a procurement specification requiring a demonstrated dry shelf life of a valve before it ever gets to see hydrazine. The ACSs for the Transtage upper stage on the TITAN III satellite launcher were procured in quantities sufficient to satisfy the launch requirements for several years. When concerns arose about the dry shelf life of the propellant TCVs, nine valves were set aside and tested periodically over a period of 5 years [1820–1823]. No changes in dry valve performance were noted.

#### 6.3.2 Latching Valves

Latching valves have the advantage over pyro valves that they can be operated repeatedly and do not require electrical power to hold them in one or another position. They are bistable valves, and the armatures are usually held in place by permanent magnets. In addition, latching valves can also act as relief valves and are designed to allow backward leakage if the pressure in the downstream section exceeds that of the upstream section (e.g., by thermal expansion of a trapped liquid volume). Such situations would be destructive if a pyro valve were used to close off a trapped volume of liquid and the liquid expanded. A low-cost all-titanium latching valve was developed that improved on the performance of existing latch valves [1824].

Sometimes it is possible to upgrade valves that had previously been used only as isolation or pressurization valves to more responsible positions in the fuel system. For instance, isolation latching valves of the same type as those that had already flown on VOYAGER were modified by replacing the EPT seat material with Teflon and using a dual-seat instead of a single-seat design. Thus modified, the valves met the reliability

requirements for RCS/ $\Delta V$  propulsion of satellite payloads to be launched by the Space Shuttle, as well as in bipropellant systems such as INSAT, LEASAT, or SAL [1825]. They could even be used as thrust chamber valves for thrusters with long burn times.

In January 1976, the Canadian CTS satellite experienced an anomaly when a latch valve was opened to fill an evacuated line [1826]. The latching valve vibrated (“fluttered”) and high-amplitude vibrations of 100 to 300 Hz with peak pressures of 8.9 to 13 MPa (1300 to 1900 psia) damaged a pressure transducer on the upstream side, causing it to short out against its casing. The downstream line did not fill completely within the allocated 3 s time after which the current was removed from the latching valve. When an attempt was made to energize the latching valve open again, it operated normally since this time there was not much  $\Delta p$  between the upstream and downstream portion of the line.

If propellant becomes trapped between two valves and experiences an increase in temperature, thermal expansion can cause a devastating increase in pressure [194]. Latching valves must be designed with the ability of backpressure relief.

### 6.3.3 Check Valves

The purpose of check valves is to prevent fluids from backing up during brief pressure spikes downstream of a check valve location. This is the main task of check valves in hydrazine systems. Check valves can be placed either on the gaseous pressurant side or the liquid propellant side of hydrazine propulsion systems. Commercial suppliers offer a wide range of check valves for hydrazine service. Check valves for pressurant gas service must still be compatible with hydrazine since vapor and condensate may accumulate next to the check valve during idle periods or negative accelerations and in temperature gradients. It is important to keep hydrazine vapors out of pressurant lines since these are usually not heated, and hydrazine condensate might freeze in the lines on the shaded side of spacecraft.

### 6.3.4 Burst Discs

Burst discs are the most reliable permanent seal of propellant passages. They are designed to burst once the propellant tank is pressurized. Since burst discs are permanently wetted on at least one side, corrosion of the thin metal may alter their designed burst pressure.

### 6.3.5 Pyrotechnic Valves

The designation “pyrotechnic valve” is usually abbreviated as “pyro valve.” In many flight applications, a valve must be actuated only once, typically a normally closed enable valve (isolation valve) that is opened at the beginning of the mission. Sometimes propulsion system branches (e.g., the apogee insertion engine branch) are shut off by firing a normally open pyro valve to avoid future trouble in case of leakage after

that initial part of the mission is completed. The lines are closed by firing a normally open pyro valve. For such applications, it is easiest and usually quite reliable to use a pyrotechnic actuator to open or close a shuttle valve, which is then rammed permanently into its new position. In most cases the high pressure generated by the pyrotechnic charge allows a fast traveling ram to shear a metal barrier to open a flow passage or to seat a plug in the flow passage to shut it off for good. The metal-to-metal seal is achieved under high pressure and friction, and often the rapidly deformed metal heats to near the melting point. Pyrotechnic valves come in two types: normally closed (NC) and normally open (NO); many satellites carry both types. NO valves may be used to isolate thrusters that have developed problems or to isolate a loop A and a bank of thrusters at the end of its useful lifetime while a redundant loop B takes over the active duty.

Some pyro valves have dual actuators or dual bridge wire initiators for increased reliability by redundancy. The initiator can have enough gas output by itself, or sometimes pellets of a gas-generating booster composition are added for additional gas output. The NASA standard initiator uses a potassium perchlorate/zirconium mixture, and the booster pellets are made from potassium perchlorate/titanium hydride, which has a higher gas output. If by mistake the driving charge is too energetic, the initiator may be ejected and become a projectile hazard to neighboring spacecraft components. This has happened in ground tests of some pyro valves.

In the early 1990s, after a string of satellite and space probe failures attributed to pyro valve explosive interaction with the hydrazine propellants, a flurry of studies was conducted on all conditions under which hydrazine propellants can be initiated to accidental explosions by activating a pyro valve. The National Oceanic and Atmospheric Administration (NOAA) published a news release on October 3, 1995, that identified a ruptured manifold as the most likely cause of the loss of LANDSAT F shortly after stage separation from the TITAN II launch vehicle in October 1993. LANDSAT F, an Earth-resources satellite, was launched aboard a TITAN II space launch vehicle from Vandenberg Air Force Base in California on October 5, 1993. Initial indications were that the spacecraft separated from the booster at the appropriate time and location but did not achieve orbit. The NOAA review board confirmed this and attributed the failure to a ruptured hydrazine manifold. The ruptured manifold rendered the satellite's reaction engine assemblies useless because fuel could not reach the engines. Consequently, there was a failure to maintain attitude control during the apogee kick motor (AKM) burn. This failure caused the spacecraft to tumble during the AKM burn and not accumulate enough energy to attain orbit.

A few months thereafter, a similar failure occurred in a communications satellite when the second of two parallel pyro valves was fired with a programmed delay sequence into a manifold that at the time was partially filled with helium and hydrazine froth. Blow-by of hot gases from the second pyro valve past a leaking ram piston is thought to have initiated a thermal runaway reaction in the hydrazine that ruptured

the tubing. This most likely sequence of events was reproduced in ground tests after the flight anomalies had occurred.

The results of industry-wide workshops were documented in a series of workshop proceedings [1827–1830], and new and improved pyro valve designs emerged in the mid-1990s. Cross sections of typical pyro valves before and after actuation are shown in Figure 52.

**Figure 52:** Typical pyro valves before and after actuation. (Republished from [1828] with permission of ©1996 American Institute of Aeronautics and Astronautics; permission conveyed through Copyright Clearance Center Inc.)

The effectiveness of O-rings in pyro valves has been questioned. There are numerous accounts where post-test inspection reported the condition of the O-rings as sheared and shredded. Testing has shown that blow-by occurred regardless of whether O-rings were installed or accidentally omitted.

The Mars OBSERVER failure in August 1993, which involved NTO and MMH instead of monopropellant hydrazine, had a slightly different failure scenario, but nevertheless pyro valves installed in Mars OBSERVER received a thorough examination as part of that failure investigation [1829, 1831, 1832]. Ground testing of flight-type pyro valves and heavy-duty, reusable pyro valve simulators with hydrazine and MMH allowed the analysis and quantification of blow-by and its effect on initiation of hydrazine explosions. Pyro valves manufactured by two suppliers, OEA and Conax, were tested, and it was found that the Conax pyro valves had less blow-by. Valves come with different bore diameters to be used in 0.25-, 0.375-, and 0.5-in. O.D. tubing systems. One pyro valve simulator was sized to represent the OEA 1420-7 stainless-steel configura-

tion. Another used a titanium alloy body. The travel speed of the ram piston could be measured with a laser Doppler interferometer. Blow-by gases were analyzed by GC and residual gas analyzer mass spectrometers. Particulates were collected and examined microscopically and counted on a Millipore filter. Another test setup simulated the geometries of TELSTAR 402 and LANDSAT F, both of which experienced in-flight failures at the moment when the second pyro valve was initiated. For the ground tests, the first pyro valve was replaced with a mechanical ball valve since the delay time between filling the manifold and firing the second pyro valve was on the order of minutes and the first valve did not need to be a fast-acting valve. The clearance between the pyro valve simulator housing and the ram could be varied by choosing pistons of different geometries. The clearance had a pronounced effect on the amount of blow-by. In one test with a 0.14-mm (0.0055-in.) clearance, there was only a mild hydrazine reaction and the peak pressure was 2200 kPa (320 psia). One test with a 0.17-mm (0.00685-in.) clearance caused a hydrazine explosion that destroyed the system and developed many fragments. The fragmentation pattern suggested that this was neither a gas-phase nor a liquid-phase detonation. It was suspected that it was related to a low-velocity detonation in a two-phase system (hydrazine froth or hydrazine with many gas bubbles). In another test, only a burst disc ruptured, but the tubing remained intact. A fourth test produced a pressure spike of 13.76 MPa (2000 psia). As a sequel to these tests, the setup was modified to reduce the hazard potential of the reaction propagating into the hydrazine supply tank and a high-speed camera was added to film the events [1833].

#### 6.4 Propellant Filters

Propellant filters have the potential to cause major operating problems with hydrazine flight systems. They may become clogged with particulate debris, increasing the pressure drop and decreasing the flow rate of hydrazines to the engines. They may act as bubble traps, accumulating small gas bubbles and then allowing a large bubble to be displaced, which may cause momentary thrust imbalance if a pair of thrusters is firing simultaneously on either side of the spacecraft. In the case of arcjets, a bubble may cause the arc to extinguish, requiring a restart, which shortens the life of the electrodes. When tabulating the wetted surface area of components suspected of contributing to gas evolution or metal leaching, the filters are the leading contributors because of the large surface area of the fine-mesh filter screen they contain. The wire mesh is often accordion-pleated to increase the particle-retention capacity. Filter screen and housing samples from CRES-304L representative of the MARINER MVM73 and CRES-304L, CRES-321, and CRES-347 representative for the MJS77 (VOYAGER) systems were tested in the JPL long-term storage tests [1160, 1161, 1638].

The most troublesome property of micrometer-sized filter screens that is often not recognized by system engineers is the tendency of liquids (cleaning agents, solvents,

water, residual hydrazine) to become trapped behind filters when one is attempting to evacuate the system in order to dry it out prior to launch or after flight use. Numerous contamination incidents have been caused by residual fluids in the propellant system. In some cases, water or hydrazine may actually freeze on the filter and evaporate/sublime only very slowly even with the best vacuum in the world applied to the suction side.

The inlets to propellant valves are usually protected by filters to retain particles that might get lodged on the valve seat and cause the valve to leak when it is commanded shut. The screen material on the filters must be compatible with the propellant, which in the case of hydrazines is not as difficult a task as with oxidizers. The corrosion product (carbazate, carbonate) film growing on the thin metal wires might cause a narrowing of the passages and increase the pressure drop or embrittle the wires. A similar wire mesh is used in surface tension propellant management devices in propellant tanks for zero-*g* operation. The long-term effects of propellant immersion on fine micronic stainless-steel wire cloth were studied for hydrazine, MMH, UDMH, and six other propellants [1834]. Immersion time histories reported in the literature ranged from 3 months to 7 years.

## 6.5 Propellant Pumps

Hydrazine is a very poor lubricant, and it is not easy to design pumps where the metal-to-metal contact surfaces do not gall after some time. The problem seems to be less pronounced with the alkylhydrazines. There is not much information on pumps used in hydrazine manufacturing plants and tank farms. Whenever possible, anhydrous hydrazine transfer is achieved by pressurization instead of with mechanical pumps. It is a lot easier to just clean out a dip tube than to clean out a pump after the transfer is completed. The new hydrazine transportation and storage 4BW cylinders introduced in the early 1990s are designed to be pressurized (the 55-gal drums were not) and the dip tube is permanently installed.

Because of the poor lubricity of hydrazine, galling of fuel pump gears during the development of the APU for the Space Shuttle was an early problem that significantly limited gear pump life [1744]. Galling problems could be reduced by decreasing the pitch velocity, by designing gear teeth to minimize sliding contact, and by selecting a very hard gear material like M2 tool steel. A fuel filter immediately behind the gear pump was installed to collect some of the abrasion products before they had a chance to plug valve and injector orifices. Despite this precaution, catalyst in post-flight APU gas generators collected sufficient iron to become magnetic.

The largest hydrazine pumps flown were those in the TITAN II, III, and IV pumping Aerozine-50 and those in ARIANE IV pumping UH-25. These pumps were driven by exhaust gases from gas generators burning fuel-rich main propellants or stoichiometric

oxidizer/fuel combinations with water coolant injection. It has always been desirable to operate propellant pumps on propellants that are already on board in order to avoid having to carry separate pump drive fluid (hydrogen peroxide) tanks, as was done on the A-4 (V-2) or the VIKING, the first planned US satellite launch vehicle, and is still in practice with the Russian SOYUZ launch vehicle.

Small missiles must rely on heavy pressurant tanks or can use hot hydrazine decomposition products from a gas generator to drive a piston pump or a set of piston pumps to feed hydrazine to the thrusters and gas generators. These propellant feed systems are best used in high-performance rocket propulsion systems with short mission durations that must operate in a thrust-on-demand mode such as for divert propulsion, evasive maneuvers, and terminal homing exercises of interceptors [1835–1837]. The exhaust from the reciprocating piston-driven piston pumps can be vented overboard or collected in a plenum for attitude control in warm gas thrusters. Flight-weight pumps with a displacement of  $106\text{ cm}^3$  ( $6.5\text{ in.}^3$ ) have a mass of under 100 g and can deliver flow rates equivalent to their own weight in hydrazine per second. Additional weight savings arise from using a lightweight, thin-walled aluminum tank instead of a tank that must withstand thousands of psi feed pressure. Using piloted solenoid valves, development units could be operated on hot gas near 1023 K ( $1400^\circ\text{F}$ ) [1838–1840]. If a pair of alternating pumps is used, a continuous stream of propellant can be delivered since one pump is expelling liquid as the other is being filled with fresh propellant. Flight-weight units use automatic warm gas pneumatic valve controls instead of solenoid valves [1841]. The same principle can also be applied to reciprocating pumps for bipropellant propulsion systems [1842]. This requires a total of four pumps, but they can share some of the controls and operate in synchrony. Small hydrazine pumps on satellites as an alternative to pressure-fed systems would allow lightweight propellant tanks and would not require as much pressurant gas as a blowdown or regulated pressure system [1843].

The ground-service equipment (GSE) fueling system for the EURECA reusable platform used a novel concept with nitrogen-driven PTFE diaphragm pumps supplying propellant directly from the shipping drums [1798].

Electrokinetic pumping offers a method to precisely meter liquid propellants under purely electrical control at pressures and flow rates well suited for microthruster applications. Electrokinetic pumping can be applied to very small microthrusters [1844]. After exploring a variety of materials and surface treatments for the electrokinetic pumping media, electrokinetic pumping of anhydrous hydrazine using both packed-capillary and larger sintered-monolith pump designs were demonstrated [1845]. Specific impulses up to 190 s have been shown for hydrazine in non-optimized capillary thrusters at a mass flow rate of  $1.5\text{ mg/s}$ . Controlled thrust pulses with a maximum continuous thrust of  $1.5\text{ mN}$ , minimum impulse bit of  $7\mu\text{N}\cdot\text{s}$ , and average specific impulse of 110 s have been demonstrated with an electrokinetically pumped microthruster assembly.

## 6.6 Pressurant Gas Selection

Obviously pressurant gases for hydrazine monopropellant and bipropellant propulsion systems must be compatible with hydrazine, which narrows the choice to nitrogen, helium, and argon. Nitrogen is often chosen because it has lower leak rates than helium. Helium has the advantage of being lighter weight where total system weight is critical, such as in lunar and planetary probes. Some of the pressurant gas selection and pressurization system design considerations described for hydrazine here apply just as well to other liquid propellants.

Pressurant gas selection depends on the type of barrier between the pressurant gas and liquid propellant. If contact times are short, as in a missile with a sealed pressurant tank during storage, less stringent purity requirements may be tolerated than in a 15-year satellite. Piston tanks may suffer from blow-by of gas, and some liquid may adhere to the walls and not get wiped off by the O-ring seals of the piston, causing adverse interaction of propellant and pressurant gas. Elastomers have some gas and liquid permeability; therefore, one must anticipate some pressurant gas/propellant interaction, although it will be slow. Oxygen contamination of the pressurant gas must be avoided because in extreme cases hydrazine will autoignite and explode with air or oxygen under pressure. Cryogenic oxygen and propellant hydrazine systems should not share a helium supply. Metal diaphragms are impermeable to either gas or liquid and allow a wider choice of pressurant gases but can be reversed only once or a few times at best before the metal fatigues.

The design of blowdown tanks or storage tanks in which the pressurant gas sits in the same tank as the liquid must allow for thermal expansion of the liquid if the tank is stored at high temperature. These considerations apply even to storage cylinders to determine the minimum size of the ullage required to accommodate the thermal expansion of the liquid and the pad pressure that is typically maintained to prevent intrusion of air during storage and shipment. Cylinders must not be overfilled with liquid hydrazine before shipment. As the liquid expands, the ullage gas bubble is compressed, and the elevated pressure allows some gas to be dissolved in the liquid propellant. It is also unusual for gas solubility in hydrazine to increase with temperature, whereas that in most other liquids decreases with temperature (see information on gas solubility in Section 2.1.12). The calculation of the necessary tank size to accept and hold a given mass of hydrazine at elevated temperature without exceeding the safe operating pressure rating of the tank is a frequent design problem facing system designers. The following variables enter this calculation: thermal expansion of the liquid, thermal expansion of the pressurant gas, thermal expansion of the tank, and solubility of the gas in the liquid [1846].

Another consideration in selecting pressurant gases is potential bubble release when the propellant is expanded to lower pressure on its way into the rocket engine. Gas bubbles may cause irreproducible impulse bits and cause arcjets to extinguish.

Gas bubbles may sensitize hydrazine to explosive decomposition upon rapid (adiabatic) compression. Dissolved gases may cavitate at the inlet of pumps unless the necessary net positive suction head is maintained [1847]. For this reason, it may be desirable to choose a gas that has very little solubility in hydrazine(s).

If propellant is rapidly withdrawn from a blowdown tank without diaphragms or pistons separating the liquid and gas phase, it will take some time before the phase equilibrium adjusts and dissolved gas is released from the liquid to restore equilibrium. This is the inverse problem of tank pressurization and propellant saturation with pressurant gas prior to launch (Section 7.5.2).

One-shot systems such as in tactical missiles using storable liquid propellants can be pressurized by warm gas from solid gas generant cartridges. It is important that the temperature at the pressurant-liquid interface not exceed the thermal stability limits of the hydrazine fuel. In some cases, the interface is formed by a metal bellows or a piston, such that the hot gases and the propellant are not in direct contact.

A significant amount of effort has been devoted to vaporizing liquid pressurants for the expulsion of hydrazine propellants [1848]. In this case, the pressurant and the propellant must be separated by metallic diaphragms or the pressurant has to be totally compatible and immiscible with hydrazine and the catalyst. Many vaporizing liquid pressurants are available. Their physical properties have been tabulated and some have been tested in ground test expulsion systems. The problem with vaporizing liquid pressurants is that the feed pressure (i.e., the vapor pressure of the liquid) is dependent on the temperature of the pressurant tank. However, as soon as propellant is withdrawn, the vaporizing liquid cools the residual liquid and the vapor pressure drops. The vaporizing liquid reservoir must be a high-heat-capacity massive tank, or one could surround it with heat-storage phase change materials to maintain the temperature a little longer and soak up heat during idle periods.

Many of the vaporizing liquids studied are fluorochlorohydrocarbons often used as refrigerants and aerosol propellants. Unfortunately, most of those react with hydrazine or poison the catalyst.

## 6.7 Flow Meters

Turbine and Micro Motion flow meters are routinely used for all three types of propellant hydrazines to meter propellant into rocket engines during ground testing and to calculate delivered specific impulse. Flow meters do not fly with rockets or satellites.

For ground testing of the liquid apogee kick stage engine for the Japanese ETS-4 satellite, a flow meter accuracy of  $<\pm 0.25\%$  was desirable to verify specific impulse accuracy of  $\pm 1$  s. To achieve this narrow level of uncertainty, an in-place, end-to-end turbine flow meter calibration system became an integral part of the thrust stand [1849], combined with digital data processing [1850]. Flow meters, valves, and pressure trans-

ducers for the TITAN II missile were endurance-tested and calibrated in a closed-loop propellant pumping system containing two 22.7-m<sup>3</sup> (6000-gal) tanks and two 984-L/min (260 gal/min) pumps for NTO and Ae-50 [1851].

## 6.8 Flight Tanks and Propellant Management Devices

A large branch of the aerospace industry has specialized in supplying pressurant and propellant tanks to the propulsion subsystem contractors and the prime contractors and commercial companies who build their own propulsion subsystems and integrate them with the payload. It is not possible to provide a complete overview of all tanks that at one time or another have been used with hydrazines or may at some time in the future be used with hydrazines. A snapshot in time of tanks that were available as of 1984 or 2001 was provided in the two earlier editions of the hydrazine book [11, 22]. It has not been possible to keep such a compilation up to date. Historical surveys of flight-weight propellant tanks have been published earlier and quickly became obsolete [1852–1854], because these survey reports unfortunately go out of date as soon as the ink dries. Just as with the valve industry, changes in product availability are occurring daily, and it is very difficult to maintain a complete and current list of flight tanks qualified for hydrazines. The only way to keep up to date with what is available in real time would be to post a tank availability list on the Internet and update it periodically. Candidate propellant tanks for hydrazine(s) include composite overwrapped tanks, tanks without PMDs, elastomer diaphragm and bladder tanks, reversible metal diaphragm and metal bellows tanks, piston tanks, and surface tension PMD tanks. The summary of flight tanks for hydrazine and MMH use that was published in 2001 in [22] has not been updated because many of the same space-qualified tanks are still in use [1855].

Surface tension and contact angles of liquid propellants must be known for the design of surface tension tanks for use in a zero-g environment in space. Surface tension tanks have fine-mesh screens in the form of chimneys, vanes, and galleries to collect and hold propellants in position near the tank outlets even in a zero-g environment, such that only liquid and no pressurant gas can enter the engines [1856–1858].

The Air Force Rocket Propulsion Laboratory (AFRPL) has conducted an extended propellant tank ground storage program that has been under way for several decades. The items included in this program can be divided into three categories: **(1)** small containers, **(2)** full-size flight-system representative tankage, and **(3)** tankage systems with associated expulsion devices. It included flight test articles as well as laboratory test tanks made from various materials (but without PMDs inserted), including five tanks each made from steels AM-350, 17-7PH, and A-286 and aluminums 2014-T6, 2021-T6, 2219-T8, and titanium-6Al-4V [1696, 1697]. In addition, some tanks, such as MARINER space probe tanks containing AF-E-332 bladders, were also included in the

test. Table 72 gives a list of reference numbers, report number, and date of publication. This table should help in keeping this very useful source of information organized (this is only useful for those readers eligible to obtain reports that may have limited distribution status). Many of these storage tests also included tanks filled with MMH or NTO instead of anhydrous hydrazine.

**Table 72:** Summary of tank storage test reports from AFRPL Edwards AFB.

| AFRPL-TR Report No. | Accession No. | Report date | References |
|---------------------|---------------|-------------|------------|
| 69-082              | AD-857561     | Apr 1969    | [1859]     |
| 70-043              | AD-875081     | May 1970    | [1694]     |

| 71-113              | AD-735288     | Nov 1971    | [1696]     |
| 72-126              | AD-755383     | Dec 1972    | [1697]     |

Storage tests with tanks filled with hydrazine are frequently conducted under desert conditions at elevated temperatures to check for pressure buildup by hydrazine decomposition on metal surfaces with which it is not compatible. Initially tanks made from 17-7PH and AM-350 stainless steels experienced some rapid pressure rise. However, when the AFRPL storage program was interrupted after 10 months and the hydrazine replaced with a fresh load of hydrazine, the rate of pressure rise was much lower [1696, 1697, 1861].

It appeared that some passivation had taken place, and most contaminants were leached from the tank surface by the first propellant load. Similar results were obtained at Bell Aerospace, where 17-7PH and AM-350 tanks were exposed to hydrazine initially at nominal 301 K (83 °F) for 1 year with numerous temperature excursions as a result of controller failure and accompanying hydrazine decomposition, which required venting of the tanks to prevent overpressurization [1862]. After the hydrazine was replaced and the temperature was held steady at 322 K (120 °F) for 3.5 years, the pressure rise from hydrazine decomposition was minimal. It is advisable to inspect test articles for possible corrosion immediately after termination of the exposure test and not let exposed tanks sit around in air until a metallurgist happens to have some time to examine them. Residual hydrazine and air (CO<sub>2</sub>) may cause additional corrosion if the test articles are not thoroughly decontaminated.

A flight-weight Al-2014 tank containing 1170 kg (2580 lb) of anhydrous hydrazine was stored in a desert climate for 46 months [1688]. At the end of that test, the tank was found to be slightly corroded. Subsequent firing tests showed the fuel to be satisfactory for combustion with NTO, but it is very doubtful whether it would have been clean enough for monopropellant use. The hydrazine content of the fuel decreased from 98.1 to 96.5% N<sub>2</sub>H<sub>4</sub>, probably by decomposition and ammonia dilution.

Storage of post-boost propulsion systems on missiles in submarines requires careful cleaning and filling procedures of the propellant tanks [1863]. In a series of controlled on-shore storage tests, it was observed that the pressure rise rate decreased with time by a factor that varied from 1.1 to 3.0 [1864, 1865]. The reasons for this wide variation were not fully understood. Removal of active material from the tank surfaces seemed to reduce the heterogeneous rate and simultaneously enhance the homogeneous rate. The predicted tank lives of 189 units tested based on the 72-h/60 °C acceptance test ranged from 10 (minimum acceptable) to 189 years. Even identical tanks filled side by side from the same drum of hydrazine varied significantly. One of the variables suspected of causing variations in the rate of hydrazine decomposition and pressure buildup was the microscopic surface roughness of the steel, in particular after pickling. It was suspected that multiple pickling operations with nitric/hydrofluoric acid (tanks recycled because they were not visually clean after the first pickling exercise) may result in increased surface roughness and increased rate of gas evolution. The nominal duration of pickling was 50 min. SEM surface analysis of CRES-304L treated in this manner showed a very rough surface and signs of severe etching and crystallographic pitting with some signs of intergranular attack. The number of allowable pickling operations should be limited in the procurement specification for CRES-304L tanks for long-term storage applications. Conversely, based on coupon testing, it was shown that electropolishing would reduce the rate of gas evolution by an order of magnitude. Another variable was drum-to-drum variation of the quality of hydrazine used.

A group of stainless-steel propellant storage assemblies (PSAs) was loaded with different batches of hydrazine that had been intentionally doped with controlled levels of CO<sub>2</sub> in the range of 30–200 ppm [1692]. The specification limit for MIL-P-26536 in effect at that time was 30 ppm CO<sub>2</sub>. Figure 53 shows the observed decomposition rates and demonstrates the distinct correlation that exists between CO<sub>2</sub> contamination and the rate of gas evolution. The rates of gas evolution were normalized for 10% ullage. The serial numbers of the PSAs (016, 036, 039) are for reference only. The design of the PSAs was essentially similar, with reversible metal diaphragms for zero-g propellant management, with spherical 1.5-L tanks serving as the source of propellant for gas generators for the expulsion of the bipropellant (GG PSA) and ellipsoid 6-L tanks serving as the source of propellant for the attitude control system (ACS PSA). The significance of these data is that it implies that the influence of CO<sub>2</sub> is associated with the heterogeneous decomposition of the hydrazine on the surface of the steel rather than homogeneous decomposition in the liquid. During a 10-year storage test at 302K (29 °C) with 15 PSAs sampled at random from a production line, the pressure in the ullage in a typical stainless-steel PSA with clean hydrazine rose from 117 to 220 kPa (17 to 32 psia).

**Figure 53:** Gas evolution rates in propellant storage tanks as a function of carbon dioxide contamination. (Reproduced and modified from [1692].)

## 6.9 Propellant Couplings and Hoses

This section on fluid connectors for hydrazine service can give only a preliminary overview of this component selection area. It is difficult to maintain a current file because the list of available components and list of potential suppliers change so frequently.

### 6.9.1 Fittings, Couplings, and Quick Disconnects

With increasing demands on the lifetime of satellites, refueling of unmanned satellites in orbit is the next major step in space operations (Section 7.5.3). Refueling is routinely done with bipropellants on the International Space Station using the Russian propulsion module. These in-orbit refueling operations require quick disconnect couplings

with a minimum of liquid leakage when making and breaking a connection. The same requirement begins to be imposed on Earth-based hydrazine transfer operations for reasons of toxicity and minimizing worker exposure. Quick disconnects initially intended for space operation will see ground-based use as well. Quick disconnect couplings described here are used not only for hydrazine but can also be used for other liquid propellants, maybe even cryogenic propellants.

Several connector companies have been active in the development of quick disconnects for hydrazine and hydrazine-based fuels. All these systems require a thorough understanding of material compatibility with hydrazine, in particular on the sliding fits of the moving parts that achieve the connection of mated parts and the hermetical sealing of demated parts against the full operating pressure on one side and vacuum on the other side. Some of the couplings were developed for automated, robotically controlled docking and mating of resupply vehicle and propellant-consuming spacecraft; other quick disconnects were designed with astronaut safety in mind, in particular with regard to residual propellant inadvertently leaking onto the surface of a space suit and dragged into the living quarters of the manned space station or shuttle following the EVA. NASA attempted to standardize the couplings such that an entire fleet of satellites could be serviced by the same tanker [1866–1868] or propellants could be transferred between satellites (peer-to-peer transfer). At least three flow inhibitors had to be installed on each side of the couplings. One of these couplings has been installed on the GRO satellite in anticipation that it might be possible to refuel it at some future time. With a standard, current technology quick disconnect, astronauts have very limited knowledge about the condition between the coupling halves at the moment they are about to break the connection. This potential problem has been solved with so-called smart disconnects, which contain additional sensors and safeguards against liquid spillage [1869]. Older connectors used since the APOLLO program and once used with hydrazine on the STS APU had a history of leakage and spills. The F-16 EPU uses a more advanced quick disconnect for the H-70 fuel.

## **6.9.2 Transfer Lines and Hoses for Hydrazine**

### **6.9.2.1 Transfer Lines for Liquid Hydrazine**

USAF safety inspectors insisted at one time that contractor use electrically conductive, carbon-filled, Teflon-lined, stainless-steel-braided flex hoses for the fueling of satellites because they were worried about the buildup of electrostatic charges in flowing liquids. Unfortunately, insufficient material compatibility testing was done before putting graphite-filled, Teflon-lined, electrically conductive hoses into service. A spacecraft may have been launched with “black” hydrazine because it was noticed too late that carbon was shed from the new hoses into the fuel. NASA has noted the blistering of similar flex hoses used for MMH service. Apparently, some agencies had been using them to avoid a perceived ESD hazard during fueling operations, but they caused worse problems than those they were trying to avoid.

### 6.9.2.2 Sampling Hoses for Hydrazine Vapors

Tubing for remote sampling by drawing air samples from outlying work areas to a centrally located analyzer should be non-reactive, non-absorptive, and impermeable to hydrazine, MMH, or UDMH vapors [1870, 1871]. There was a case where for many years animal exposure cages were overdosed accidentally because the hydrazine arriving at a central monitoring station after traveling through very long tubing was only a fraction of what was in the exposure chambers of the animals. Most of the hydrazine had absorbed into or diffused through the tubing, and some became oxidized. The published animal exposure toxicity data obtained with this faulty analysis technique should have been invalidated. Hydrazine decay during transfer in the sampling lines was not measured.

## 6.10 Propellant Gauging (Gaging)

Sight glasses, floats, or other liquid-level gauging methods that are commonly used on the ground are no longer working in space in a zero-*g* or low-*g* environment. Commercial satellite operations are a multi-billion-dollar industry whose revenue is often dependent on the accuracy of predicting the remaining life of a satellite as it nears its end of life. This information is needed in planning satellite replacements, in transponder leasing contracts, and in squeezing maximum revenue out of existing space assets. In crowded geostationary orbits with a limited number of orbital slots, enough propellant must be reserved for moving the exhausted satellite to a graveyard orbit or de-orbit it altogether. Incorrect propellant gauging information may result in bubble ingestion, loss of pressurant gas, or uneven thrusting and spacecraft tumbling out of control when thrusters need to operate in pairs and one of them is starved of propellant. Considering how important this information can be, it is surprising how few propellant gauging systems have been tested or even flown. The propellant gauging methods described here for hydrazine work equally well for NTO and MMH. Many possible gauging techniques that might work in zero-*g* are quite susceptible to low-*g* disturbances [1872]. Problems are caused by ambiguous liquid orientation, bubble entrapment, sensor wetting, and reduced convection. Techniques evaluated in sub-orbital parabolic KC-135 flights include (1) an ultrasonic point sensor system, (2) a nucleonic gauging system, (3) an ultrasonic torsional wave guide, and (4) an ultrasonic flow meter [1873]. Other gauging methods suggested were (5) IR-absorption trace gas, (6) integrating flow meters [1874], or (7) detection of resonant acoustic mode shifts due to changes in the tank's effective mass [1875]. Despite all these efforts, there remains an uncertainty about the accuracy of propellant gauging systems for spacecraft in orbit [1876].

Accurate temperature and pressure telemetry may enable ground controllers to calculate the amount of remaining propellant in a blowdown tank from PVT equa-

tions [1877]. This method would be applicable to any liquid propellant, not just hydrazine.

Every drop of hydrazine in orbit is worth more than its weight in gold. For communication satellites, just 1 lb hydrazine more or less can translate into about \$2.5 million in revenue difference by extending the useful life of a satellite.

Short of having actual liquid level telemetry data (it is not known whether any of the satellites currently using hydrazines have this capability), the filling level of tanks can sometimes be implied from the telemetry of tank temperature increases after the satellite enters sunlight or after tank heaters have been turned on. This was the method used in G-STAR III as it approached its end of life in orbit after the station keeping propellant was exhausted early. An estimate of remaining propellant was needed to rescue it and move it from a faulty transfer orbit to 24-h GEO [1878]. Temperature variations between the two pairs of tanks cause unequal helium expansion, leading to thermal pumping of the hydrazine between tanks on a daily basis. This thermal pumping had the potential of depleting all the hydrazine from one tank and pressurant gas entering the propellant lines leading to the thrusters, resulting in loss of pressurant and loss of impulse reproducibility. By selectively turning tank heaters on and off, the flight controllers had a limited method of distributing the propellant evenly to keep this from happening too soon. One group of hydrazine monopropellant tanks in the Indian Remote Sensing (IRS) satellite emptied much earlier than expected [1879]. Temperature differences in the tanks were blamed for this anomaly, and after-the-event calculations showed how much propellant imbalance would have to be expected for a given  $\Delta T$ .

Using tank temperature and tank heater energy input telemetry, it is now possible to fairly accurately predict the amount of residual propellant in surface tension PMD tanks in satellites in orbit, allowing extension of useful mission duration and leaving just enough propellant to do the controlled graveyard orbit decommissioning burn [1880–1882].

Even in spin-stabilized satellites such as the HS-376, where the whereabouts of the propellant should be well known (as opposed to three-axis stabilized satellites), propellant gauging has not always been an easy task [1883]. Using tank pressure (PVT method) measurements during the blowdown of four conospheroid tanks in combination with thrusting bookkeeping for cumulative propellant consumption derived from  $\Delta V$  and known  $I_{sp}$  performance of the 5-lb<sub>f</sub> thrusters, it was possible to obtain remaining propellant measurements with satisfactory accuracy. Hughes had the rare opportunity to verify their propellant gauging method based on telemetry data when two wayward satellites were plucked from orbit by daring Space Shuttle astronauts and brought back to the surface, where the off-loaded propellant was weighed and compared to the bookkeeping by PVT methods and found to agree within a few percent accuracy. Much improved accuracy was achieved by Hughes Space and Communications Co. in its large HS-601 geostationary bipropellant satellites using high-resolution pressure transducers and brief pulsing of the pressurant valves between existing

pressurant tanks and propellant tanks [1884]. Momentary opening of the interconnect valve results in periodic re-pressurization of the propellant tanks. Measurements of pressures in the propellant tanks before and after re-pressurization make it possible to determine the gas volume in the propellant tank, which translates into propellant volume and propellant mass knowing the total volume of the tank and the density of the propellant. The re-pressurization capability offers the additional advantage of closely controlling the oxidizer : fuel ratio for maximum delivered  $I_{sp}$ .

### 6.11 Other Components

It is unfortunate that the freezing point of hydrazine is relatively high, close to that of water. A system designed to operate in outer space, including Earth's shadow, must be designed to keep hydrazine above freezing. The thermal design of spacecraft is a science by itself. All the way from the propellant tanks to the thruster inlet, temperature must be maintained by a series of tank heaters, line heaters, valve heaters, and catalyst bed heaters. These components along with their controls and power distribution lines add to the complexity of hydrazine propulsion systems. Some of the upper stages of launch vehicles, such as the Inertial Upper Stage (IUS), had to operate as the upper stage of expendable launch vehicles (TITAN) as well as in the payload bay of the Shuttle STS. For TITAN launches, the mission was completed in a few hours, but if carried to low Earth orbit by the STS, the IUS may spend several days in the payload bay before it can be launched. For those situations, electric heaters are used to protect the hydrazine system from freezing, and multi-layer insulation (MLI) blankets are used to reduce the heat loss from the solid rocket motors. In addition, the payload satellite or space probe may also contain hydrazine that has to be kept in the liquid state. Sub-system and system vacuum chamber tests were conducted to confirm the thermal design and analysis of the hydrazine system under these conditions [1885].

The concern about inadvertently freezing hydrazine lines in satellites and upper stages has led to the development of self-regulating line heaters such as the Raychem Thermolimit heater tape used on the CENTAUR upper stage [1886]. Since the main propellants of this upper stage are cryogenic oxygen and cryogenic hydrogen, some parts of the stage may get very cold, cold enough to freeze hydrazine used in the RCS. The operating principle of the Thermolimit tape is based on the observation that the resistance of a conductive polymer (Kynar) increases with temperature, but so does its specific volume, reducing the cross section across which current can flow. It should be mentioned that Kynar is not compatible with hydrazine. It is important to avoid spills of hydrazine propellant on Kynar heater tapes.

If the temperature controller of line heaters fails closed, the lines may inadvertently become overheated. The worst-case scenario of overheated propellant lines was simulated in dynamic and static ground tests [1173].

## 7 Handling of Hydrazine

Because of the toxic and corrosive properties of hydrazines, these compounds should not be handled in the literal sense of the word, that is, with bare hands or in close contact with the skin. The toxic and corrosive properties of hydrazines make it mandatory that precautions necessary for safe handling be sufficiently understood. Once the proper precautions for storage and transfer of hydrazines have been taken, hydrazines can be handled as safely as any other hazardous chemicals. It is the objective of this section to provide the hydrazine user with at least the most important information to get the job done safely and successfully. This chapter is the chapter for anhydrous hydrazine, but many of the considerations for safe handling of hydrazine are the same as those for methylhydrazines, which are discussed in other chapters of *Encyclopedia of Liquid Fuels*.

One of the main applications for hydrazines is in space propulsion. Space propulsion system hazards for hydrazines and other rocket propellants are summarized in the *Space Propulsion Hazards Manual*, a three-volume series useful for planning of ground service equipment (GSE) and fueling operations [1887–1889]. Storage and transport of large quantities of hydrazines constitute a potential corrosion, flammability, and toxicity hazard and must be carefully planned to avoid uncontrolled release of hydrazines in either liquid or vapor form. First sources of information on handling and storage of hydrazines are the manufacturer's product data sheets [1645, 1890], safety data sheets, and publications by the US federal government.

Disposal and spill cleanup of hydrazine fuels has been practiced for many decades, and there exists a good database on available methods for safe handling of this fuel, for instance Chapter 2 in [1891].

### 7.1 Design of Storage Facilities

Hydrazine storage facilities are needed at the point of production, as a method of government stockpiling of strategically important fuels, at the point of consumption to assure against interruptions of supply, and, finally, for the storage of waste propellant waiting to be reprocessed or destroyed.

One of the largest storage and mixing facilities for propellant hydrazines during the 1960s was the Rocky Mountain Arsenal near Denver, CO. This facility could store hundreds of thousands of gallons of various hydrazines and was also in charge of mixing Aerozine-50 from its ingredients. The Rocky Mountain Arsenal storage and mixing facility was closed in the late 1970s amid accusations of improper housekeeping procedures and environmental pollution (Section 7.12). In 1988, Olin Chemicals opened a new hydrazine storage and mixing facility in McIntosh, AL, which was mostly devoted to blending and storing Aerozine-50 but also had limited storage capacity for some MMH.

**Storage Compatibility Requirements and Setback Requirements for Liquid Propellants.** Quantity-distance regulations for liquid propellants and explosives were once set forth in two US Army safety manuals [1892, 1893]. The first manual, in Section 15, pages 15–1 through 15–27, contains a section on quantity-distance storage criteria for liquid propellants and categorized all propellants into four hazard groups, I through IV, then designated six storage compatibility groups, A through F. Hydrazine, MMH, UDMH, Ae-50, and mixed amine fuels have been classified in Hazard Group III and Storage Compatibility Group C. A 200-kg (440-lb) drum of anhydrous hydrazine in unprotected storage requires a setback of 180 m (600 ft) from inhabited buildings, public traffic routes, and other storage structures containing incompatible propellants. If the drum is in a protected bunker, the setback requirement is reduced to 39 m (130 ft). For 10 drums of hydrazine, the unprotected setback is still the same, 180 m, but the protected setback is increased to 63 m (210 ft). Additional quantity-distance regulations for explosives (most are much more hazardous than liquid hydrazine) are described in the Department of Defense (DoD) *Contractor's Safety Manual for Ammunition and Explosives* [1894] and the Department of Energy (DoE) *Explosives Safety Manual* [1895–1897]. These manuals are not always directly applicable to hydrazine and are listed here only as examples of how quantity-distance requirements were derived. The standards applicable to energetic liquids have been reviewed [1898] and need to be updated periodically.

## 7.2 Applicable Storage and Transportation Regulations and Recommendations

This section constitutes only an incomplete summary of regulations and recommendations affecting the storage and transfer of hydrazines. Regulations change daily, and the hazardous materials coordinator for a chemical company or rocket test site will need to follow updates on a day-to-day basis. This is a full-time job.

### 7.2.1 Applicable Government Regulations

The transportation of hydrazines in interstate commerce must comply with the Code of Federal Regulations CFR 49, § 172.101. According to the 1987 revision of that document, anhydrous hydrazine was then classified as a **Flammable Liquid** and **Poison**. The shipping classification of anhydrous hydrazine has changed several times during the past 50 years. At one time, anhydrous hydrazine carried only a **Corrosive Liquid** label. Now the segregation requirements from other cargo are still the same as for Corrosive Liquid. Prior to 1987, hydrazine hydrate required only the **Corrosive Material** label. Because regulations change frequently, it is advisable to check the most recent revision for the applicable requirements before shipping hydrazines. Hydrazine, MMH, and UDMH are or were shipped in containers of the types listed in Table 73.

Normally, the Department of Transportation (DOT) requires all rail cars or tanker trailers to be hydrostatically tested every 5–10 years. However, because of the age of

**Table 73:** Transportation containers for hydrazine fuels.

| Fuel                                                                 | Type of container          | DOT specification                     | Metal                                  | Safe volume capacity (at 10% ullage) |                   | Load capacity |       | Tare mass |         | Max. allowed differential press. inside – outside |                                         | Safe to apply vacuum to container? |

Data sources: [1899–1901]

some of the aluminum tank cars still in use in the late 1990s, the testing requirement was increased to annually.

As one example of the continual changes being made to transportation regulations, which make it very difficult to maintain an up-to-date file, one can refer to the announcement in FR **63**, No. 132, pp. 37453–63 announcing changes made to the requirements that tank cars for hydrazine, MMH, or UDMH have pressure relief valves. Special Provision B7 was added for the entries “Dimethylhydrazine, unsymmetrical,” “Hydrazine, anhydrous or Hydrazine aqueous solutions with more than 64% hydrazine, by mass,” and “Methylhydrazine.” DOT exemptions, DOT-E 11200 and DOT-E 11490, authorize the shipment of hydrazine materials in multi-unit tank car tanks *without* pressure relief devices. A hydrazine manufacturer also sponsored a risk analysis that focused on the transportation of propellants that are toxic and the risks associated with those materials when transported in multi-unit tank car tanks equipped with or without safety relief devices. The results of the analysis determined that there was an increased likelihood of the release of toxic materials when a pressure relief device is present.

A new class of mobile equipment has been designed for the dedicated transport of NTO ( $\text{N}_2\text{O}_4$ ) and MMH liquid rocket propellants [1902]. The existing equipment, operated under special permit, became obsolete in the late 1980s as a result of new DOT regulations. New regulations focus on increasing public safety and reducing the risk of environmental impact. The design and construction of a prototype vehicle was completed concurrently with the development of new DOT rules and specifications. The basis of the new design was a 2.06-MPa (300-psig) ASME pressure vessel, packaged as a semi-trailer with several noteworthy safety features. It was designed to withstand a frontal collision, lateral impact, rollover, and external fire without breaching the pressure integrity of the lading vessel.

### 7.2.2 Reportable Quantities of Hydrazines under SARA Title III

The presence of Extremely Hazardous Substances (EHSs) in quantities in excess of the Threshold Planning Quantity (TPQ) requires certain emergency planning activities to be conducted. A consolidated chemical list including chemicals subject to reporting requirements under Title III of the Superfund Amendments and Reauthorization Act of 1986 (SARA), also known as the Emergency Planning and Community Right-to-Know Act (EPCRA), and chemicals listed under Section 112(r) of Title III of the Clean Air Act (CAA) of 1990 was posted on an EPA web site for distribution and downloading in November 1998. This so-called mother of all lists was prepared to help firms handling chemicals determine whether they need to submit reports under Sections 302, 304, and 313 of SARA Title III (EPCRA) and, for a specific chemical, what reports may need to be submitted. Accidental releases of Comprehensive Environmental Response, Compensation and Liability Act of 1980 (CERCLA) hazardous substances, in quantities equal to or greater than their reportable quantity (RQ), are subject to reporting to the National Response Center

under CERCLA. Such releases are also subject to state and local reporting under section 304 of SARA Title III (EPCRA). The provisions of the act are found at 40 CFR Parts 350 through 372. SARA Title III has two distinct goals: (1) to encourage and support emergency planning for responding to chemical accidents and (2) provide local governments and the public with information about possible chemical hazards in their communities. The TPOs for various hydrazines are summarized in Table 74. As of March 2022, this information was available at <https://www.gpo.gov/fdsys/pkg/CFR-2016-title40-vol30/pdf/CFR-2016-title40-vol30-part355-appA.pdf>.

**Table 74:** SARA Title III List of Lists, Consolidated list of chemicals subject to Emergency Planning and Community Right-To-Know Act (EPCRA) and Section 112(R) of Clean Air Act (CAA), as amended November 1998.

Data source: 40 CFR Parts 302 and 355

EPA tries to keep track of the path of hazardous chemicals as they wend their way through chemical processing into other chemicals or end uses. The Toxics Release Inventory (TRI), published by the US EPA, is a valuable source of information about toxic chemicals that are being used, manufactured, treated, transported, or released into the environment. Hydrazine, MMH, and UDMH and some of their production waste products are on this list. It was estimated that discharges of hydrazine into surface water (presumably in the form of boiler condensates and blowdown) had decreased from 12600–9000 kg (28000–20000 lb) in 1987–1988, though it is unclear whether this reduction was a result of more efficient effluent cleanup methods or a decrease in overall usage. Even with the reductions there may still be concern for aquatic toxicity. However, the concern for air releases was not mitigated by the apparent decrease in water releases. Because EPA is concerned with large air releases of hydrazine, it was suggested in 1990 that it would be placed on the Risk Reduction Candidate List until more data were made available. In addition, hydrazine will be added to the Master Testing Candidate List for developmental toxicity. It is not known why hydrazine was singled out among 479 chemicals on the EPA CAA Section 112 list in 1998 to be one of the 33 high-priority chemicals suspected of posing the “greatest potential threat to public health in the largest number of urban areas” [1903, 1904].

### 7.3 Hydrazine Ground Service Equipment

Hydrazine storage and hydrazine transfer into the satellite or upper stage were once separate functions. The transfer equipment, propellant loading carts, were part of the ground service equipment (GSE). Fueling tasks were simplified when the two functions could be combined.

The Generic Propellant Transfer Unit (GPTU) is a top-loading, top-unloading, vertically oriented DOT Code 51 cylinder designed primarily for storage and transfer at launch sites, but it also has DOT approval to transport propellants on public highways [1905–1908]. This unit serves double duty as a storage and transfer tank from the manufacturer to the launch site storage area and then to the space vehicle without the need for intermediate transfer and without the risk of inadvertent contamination during intermediate transfers. Of course, the 500-gal unit is only suitable for very large spacecraft. The tank is nested in an insulated crash protection jacket, which itself is pressurized with inert gas. The valving is configured to allow propellant circulation for thermal conditioning. Overall, the tank is 1.62 m (5.33 ft) in diameter and stands 2.4 m (8 ft) tall. The GPTUs are normally provided on their own dedicated trailers. The tanks sit on feet equipped with load cells and readout units to indicate the weight of the unit accurately to within a pound. Both single- and double-tank trailers are in use, and both versions have permanently mounted access platforms; the double-tank trailer has a control panel that integrates both tanks into a single piping system. The units have lift points where they can be lifted by a forklift from below or a crane from above. As of 1993, the GPTU was qualified for use with monopropellant-grade hydrazine, high-purity-grade hydrazine, MMH, and NTO/MON.

Prior to the introduction of the GPTU and pressure-resistant 4BW cylinders, there had been a multitude of propellant fueling carts in a fleet of GSE, each one designed for only one specific satellite program, lacking commonalty and interchangeability. Each cart required its own operating team, and carts often needed to be off-loaded, rinsed, and decontaminated between launches, creating large volumes of wastewater. However, while the fueling carts were equipped to transfer hydrazine *and* pressurize the tanks on the satellite with helium or nitrogen pressurant gas, a GPTU could do only the hydrazine transfer and flight tank pressurization still had to be provided from a separate GSE unit.

Looking back at the history of the 55-gal barrel replacement, the 250-gal DOT110A500W cylinder was first qualified by Hughes Space & Communications Group and is now widely used by other satellite and launch companies. The same design was initially qualified for use with NTO and MMH. It can now be used for anhydrous hydrazine, hydrazine solutions, and UDMH as well.

The NASA KSC web site maintained by the Liquid Propellants and Fluids Management Office lists a range of cylinders that can now be used to dispense, store, and transport anhydrous hydrazine and MMH [1909–1911]. A summary of these cylinder tanks is presented in Table 75.

**Table 75:** Hydrazine fuel cylinders in use at NASA KSC.

|                                                              | Nominal cylinder size, gal  |                             |                             |                             |                             |

| Net capacity, gallons, at 10% ullage                         | 4.5                         | 27                          | 31                          | 50                          | 108                         |

A 30-gal cylinder is a top-loading, vertically oriented cylinder. Allowing 3-gal ullage for thermal expansion, it will hold 27 gal of liquid. It has a 46-cm (18-in.) diameter and stands 1.12m (44 in.) tall. The 30-gal container was sized specifically such that it could be manhandled by self-contained air-breathing protection ensemble (SCAPE)-suited personnel. It fits very well on a hand truck for moving it around the storage yard or into position for fueling of small spacecraft.

There are four different sizes of DOT4BW cylinders available at KSC/CCAS that can be used for hydrazine, MMH, or UDMH [1908]. All share a common heritage with the original NASA-designed 30-gal version. “DOT4BW” refers to the Department of Transportation design specification. There are various exemptions to existing DOT specifications primarily due to being constructed of 304L stainless steel, which was not always recognized as an “authorized” material for this classification of containers. All cylinders have a built-in dip leg (standpipe). A sight glass is not required because normally the cylinders are placed on a scale to determine their content. Their operating pressure ranges from full vacuum to 688 kPa (100 psig), and the maximum allowed working pressure is 1548 kPa (225 psig), except for the 128-L (34-gal) cylinder, where the maximum allowable working pressure is 2064 kPa (300 psig). The connections have a 0.5-in. KC male thread. The advantage of the cylinders is that they allow pre-saturation of propellants with pressurant gases during storage. Pre-saturation is a time-consuming operation that often had to be carried out in dedicated separate GSE equipment at launch sites, but now pre-saturation can be achieved while the cylinders are in transfer or in storage. The cylinders do not have a pressure relief valve or a burst disc. The GSE compressed gas control panels from which the cylinders are pressurized for propellant transfer must still carry relief valves and burst discs.

A small 5-gal “model A” cylinder (which actually holds 4.5 gal of liquid) is essentially a scaled-down version of the 30-gal cylinder, suitable for small experimental users. As of 1993, an additional overpack was still required to ship MMH in either a 30- or 5-gal cylinder.

Government regulations can be the inadvertent cause of safety hazards in situations where the initial intent was to avoid hazards. For instance, 49 CFR § 173.276(a)(2) prescribed the shipping of hydrazine in glass bottles (not exceeding 1 gal capacity each) in vermiculite in a metal can in vermiculite in a wooden outer box. There have been incidents where hydrazine leaking into vermiculite autoignited in air because vermiculite has a large surface area and contains traces of transition elements that act as catalysts. The ignition and the fire add to the toxicity hazard of a leak. Alternative packaging materials should be evaluated to replace the vermiculite in the government regulations. Several regulations, e.g. 49 CFR § 173.276(a)(1) Specification 1D or 1M, also referenced in [1912], p. 4–19, allowed the use of bottles packed in expanded polystyrene packaging materials. That does not seem to be a good choice for anhydrous hydrazine either!

Safety tests used for the classification of transportation hazards of anhydrous hydrazine in France were very similar to those used in the United States [1913]. The Standard Transportation Commodity Code for anhydrous hydrazine is 4906225, and for aqueous solutions of hydrazine hydrate it is 4935030. The United Nations identifier for anhydrous hydrazine is UN2029, for aqueous solutions of hydrazine hydrate containing less than 64%  $\text{N}_2\text{H}_4$  it is UN2030, and UDMH and MMH go under the UN Identification numbers UN1163 and UN1244, respectively. The Hazardous Materials Diamond described in NFPA Nos. 49 and 704 for anhydrous hydrazine is shown in Figure 54.

**Figure 54:** Hazardous materials diamond for hydrazine in accordance with NFPA704 [1914]

The Hazardous Materials Diamond ranks hazard properties on a scale from zero (no hazard) to 4 (worst hazard). For anhydrous hydrazine, most MSDSs have a 3 for flammability (red), a 3 for health hazard (blue), and a 2 for reactivity (yellow), where a 3 in the Health field describes a chemical “extremely hazardous to health,” a 3 in the Flammability field describes a “liquid that can be ignited under almost all normal temperature conditions,” and a 3 in the Reactivity field describes “materials which in themselves are capable of detonation or of explosive decomposition or of explosive reaction but which require a strong initiating source or which must

be heated before initiation.” A 2 in the Reactivity field describes “materials which in themselves are normally unstable and readily undergo violent chemical change but do not detonate.” Some safety-related web sites show the Hazardous Materials Diamond for hydrazine with a 3 rating in all three top fields of the diamond.

## 7.4 Recommendations for Safe Storage of Hydrazine

Hydrazine can be handled safely as long as the personnel doing the fueling work are properly trained and obey the safety regulations and the equipment is in perfect working order. There exists a long history of safe handling and storage in the industry [1915] and with organizations that routinely transfer hydrazine at launch sites [1916].

In addition to government-issued regulations, some industrial organizations have issued recommendations for the safe storage of hydrazines. Among those are recommendations from hydrazine manufacturers who undoubtedly have the best experience in the safe handling of the material. These recommendations are shown on the product data sheets and MSDSs. Product data sheets and MSDSs must be updated periodically. Hydrazine users must maintain a set of the most recent versions of these sources of information in their records. Links to web sites where this information can be downloaded must be updated periodically. In addition, Factory Mutual Research has issued and periodically updates a Loss Prevention Data Sheet on hydrazines that provides recommendations on spacing of outdoor storage tanks in a tank farm and the type of water sprinklers that should be used to protect tanks from a spreading fire [1917].

## 7.5 Hydrazine Transfer Procedures

### 7.5.1 Transfer from Surface Transport Containers

In the 1970s and 1980s an average of about 5700 metric tons (5.2 million lb) of hydrazine fuels were moved over about 322000 km (200000 mi) of public highway in the United States each year, so there was a remote possibility of spillage along these routes. So far, no major anhydrous hydrazine spill has occurred en route. The track record of anhydrous hydrazine transportation has been clean [1900, 1918]. There is one case where a storage area was inadvertently flooded by a sprinkler that went off without a fire alarm and a storage tank was floated and some of the contents spilled.

Estimated annual movements of hydrazines in the United States in 1977 were as follows:

- 1430 metric tons (1.3 million lb) hydrazine
- 550 metric tons (0.5 million lb) MMH
- 1542 metric tons (1.4 million lb) UDMH
- 2203 metric tons (2.0 million lb) Aerozine-50 mix

Not all of this consisted of new hydrazine fuels. Some of it may have been waste fuel being moved to disposal sites. Sometimes propellant is moved between government installations because it is no longer needed when a program is canceled. As of 1977, all six hazardous materials incident reports involving hydrazines were caused by leaking 55-gal drums. In the late 1990s, all US government-owned drums were retired and replaced by cylinders. The 55-gal cylinders have now replaced the old 55-gal DOT5C/UN1A1 drums (which are no longer available at NASA KSC/CCAS Controlled Storage).

In 1995, NASA KSC requested that NASA WSTF provide 2500 gal hydrazine to support Space Shuttle operations. A KSC tanker loaded the propellant for transportation to KSC and the transfer was completed safely. The propellant was originally stored at WSTF to conduct Space Station Freedom propulsion module testing but was no longer needed there when NASA decided to use a Russian propulsion module instead. A brief description of Air Force practices for the transport of hydrazine is published at [1919].

Tank cars usually have a standpipe through which liquid can be withdrawn. Before unloading is done, the drums and other equipment should be electrically grounded. Before a drum is discarded, it must be filled and flushed with water. Manufacturers of hydrazines recommend storing the propellants under a slightly positive pressure of a blanketing gas (nitrogen) to prevent intrusion of atmospheric carbon dioxide by “breathing” of the tank during storage temperature fluctuations.

In terms of total tonnage, much more hydrazine is transported in the form of hydrazine hydrate and hydrazine solutions than in anhydrous form. In view of the wide distribution network and the many forms of transport, it is not surprising that occasionally transportation incidents with hydrazine solutions happen despite all precautions taken in transporting hazardous chemicals. One isolated incident was caused by the derailment of a train, causing a spill of hydrazine hydrate from 16 punctured steel drums in a railroad accident near Sea Cliff, CA, on July 28, 1991. No major environmental damage occurred since the spill site was quickly surrounded by a dam and leaked hydrazine hydrate was destroyed with hypochlorite solution.

Regardless of whether small or large quantities of hydrazine must be transferred, it is imperative to avoid exposure of anhydrous hydrazine to ambient air. Otherwise, serious contamination and system failure may result from the absorption of atmospheric contaminants. The surprisingly fast take-up of water and carbon dioxide was demonstrated by exposing a 25-mL sample of anhydrous hydrazine in a beaker (16.3 cm<sup>2</sup> surface, 1.5 cm deep) to air at 829 mbar (630 mm Hg) and approximately 30% ambient RH [110]. The low ambient pressure of the high-elevation test site should have had little effect on the rate of contaminant absorption, and similar results can be expected at sea-level atmospheric pressures of 1 bar. The water content of the sample increased within 24 h to 38% and began to level off near 50% after 4 d, whereas the carbon dioxide concentration showed a steady climb throughout the 4-d test period to 33% CO<sub>2</sub>. The average rate of increase was 50 ppm CO<sub>2</sub> per minute.

In terms of total weight of hydrazine consumed, the transfer of hydrazine solutions to boiler feedwater treatment facilities exceeds the amount of anhydrous hydrazine fueled into space vehicles. Consequently, in view of tightening occupational exposure limits and concern about the potential carcinogenicity of hydrazine solutions, the electric power industry and steam plant operators in cooperation with hydrazine suppliers have overhauled and upgraded the handling and transfer procedures for hydrazine solutions in power plants, established safe handling practices for hydrazine solutions, and provided equipment that allows closed-system transfer of solutions with a minimum of vapor formation.

### 7.5.2 Launch Site Ground Service Equipment and Propellant Carts

Propellant service carts are used to load an accurately measured amount of hydrazine into a satellite or spacecraft. Because this is done as one of the last operations immediately prior to launch, the fuel must be metered from the cart because it would not be accurate enough to weigh the launch vehicle plus payload before and after loading the hydrazine. Most satellites are loaded with hydrazine before they are stacked on top of the launch vehicle, so it would be possible to weigh the receiving unit. Both volumetric and gravimetric metering has been used by various propellant servicing carts built for Intelsat III, Pioneer, Atmospheric Explorer, or RCA Satcom with hydrazine loads ranging from 18 to 1711 kg (40 to 3770 lb), but that is now history [1920]. The carts also supplied compressed helium or nitrogen at 2.7–4.1 MPa (400–600 psia) to pressurize the fuel tanks.

Until 1992, the monopropellant RCS system in the CENTAUR upper stage flown on TITAN or ATLAS was fueled directly from 55-gal drums. The CENTAUR contains two tanks that must be fueled with 77 kg (170 lb) of hydrazine each. Because the shipping drums could not be pressurized sufficiently (actually the shipping drums were not intended to be pressurized!), this was a very slow procedure. The procedure could be accelerated by designing and building a Hydrazine Automated Loading System (HALS) propellant cart with an ASME-code-compliant pressure tank capable of pressurized transfer of 300 L (80 gal) of hydrazine at 930 kPa gauge (135 psig) [1921]. Two redundant flow meters measured and integrated the mass flow. The cart also carried 37 L (10 gal) each of demineralized water and IPA. The water was used to displace the residual hydrazine from the manifold and hoses after the fueling. The IPA was used to displace the water and allow for easy drying by evacuation.

Temperature conditioning of propellants about to be metered by flow meters is important to obtain the accurate density. Pressurant gas saturation of propellant to be transferred is also important. If the propellant is oversaturated, bubbles will be released during transfer and the metering becomes inaccurate. If the propellant is insufficiently saturated, it will take too long to achieve equilibrium while it is stagnant and sitting on the launch pad before the pressure of blowdown systems can be topped off. It is interesting to compare pressure histories of tanks during the prelaunch period.

Pressure changes occur due to pressurant gas absorption and temperature fluctuations/temperature gradients in the payload shroud [1922, 1923]. Many payload shrouds are actively temperature conditioned with forced air (gas) convection during launch preparations to make sure that propellant loads are balanced between communicating tanks. Because numerous launch sites are in hot climates (Florida, Guayana), temperature conditioning of the shroud is not always easy.

One of the approaches to simplify fueling transfer operations led to the development of the Olin Propellant Servicing Unit (PSU) for either grade of monopropellant or high-purity-grade hydrazine and directly applicable to methylhydrazines and their blends [1924, 1925]. The Olin PSU replaced conventional propellant servicing carts but can deliver propellant at much higher pressures (up to 3440 kPa = 500 psig) and with a minimum of SCAPE suit operations. Conventional propellant carts such as those used for Delta Star, Brilliant Pebbles, or ERBS shown for comparison were much more complex and required substantial on-site support for decontamination and propellant quality control. In contrast, the Olin PSU requires only a minimum of support at the launch site. The only facility support needed is the vapor scrubber for the hydrazine vapor-saturated pressurant  $\text{GN}_2$  bled after completing the propellant transfer. The Olin PSU is filled at the manufacturer with a pre-weighed accurate amount of hydrazine to exactly meet the requirements of one satellite load. The load is drained into the spacecraft “to the last drop,” similar to a bag of intravenous fluid administered to a hospital patient by prescription of the doctor. All connections on the emptied unit are then capped and the unit is returned to Olin for refilling. One of the first applications of the Olin PSU was for fueling the Atmospheric Composition Explorer (ACE) satellite launched in August 1997. This particular satellite was a “spinner” and did not contain diaphragms. That made it possible to fill the system through the same fill and drain valve that was used to apply tank pressurization.

For satellites where the manifold is filled with hydrazine prior to launch, such as SPOT 4, it is common practice to deliberately leave a helium bubble gas cushion at the thruster end of the line to accommodate thermal expansion of the liquid as a result of ambient temperature fluctuations. For some large satellites, such as the Polar Platform Propulsion Subsystem used for ENVISAT, the propellant lines between the tanks and the thrusters can be up to 13 m long, leaving a disproportionately large gas bubble at the end of the line and introducing uncertainties about the location of the gas bubble. An analysis was conducted by the designers of ENVISAT to determine the adiabatic compression hazard potential upon sudden filling of the manifold and the compression of gas bubbles at the end of a long run of tubing and to select an acceptable bubble size [1926]. One may not assume that the gas is evenly distributed among the eight thrusters, and gas bubbles will be of varying sizes, requiring different valve opening times to expel gas bubbles once the satellite is launched. It was difficult to predict impulse delivered if the first slug of propellant was a mixture of hydrazine and gas. The line volume in one half-system of ENVISAT was 761 mL compared to only 180 mL for a SPOT 4 system (from which ENVISAT was derived). As a result of this larger volume,

the manifold filling and gas priming procedure had to be changed from that practiced for several launches of SPOT satellites. As a result of the computer analysis and inert fluid testing, a different propellant loading strategy was developed.

A hydrazine transfer vehicle intended to fuel a hydrazine auxiliary power system on a large military aircraft was designed to hold up to 1040 kg (2300 lb<sub>m</sub>) of hydrazine in a single tank with 10% ullage, capable of transferring the hydrazine by pressurization with GN<sub>2</sub> to 342 kPa (35 psig) into the aircraft [1927]. The tank had three top penetrations, but none at the bottom. The top penetrations carried a dip tube, a pressure relief valve set at 410 kPa (45 psig), and a GN<sub>2</sub> connection for inert gas blanketing and pressurized transfer. The design of hypergolic propellant GSE for fueling launch vehicles and satellites at NASA KSC is outlined in [1928].

Pre-packaged gas generators for a submarine emergency deballasting system are routinely filled on shore with hydrazine in an operation very similar to fueling a satellite or an upper stage [1929].

### 7.5.3 In-Orbit Refueling with Hydrazine

In the near future it may be possible to routinely transfer hydrazines between tanker vehicles and unmanned US spacecraft. It has been predicted that within 10 years, in-orbit servicing will become so common that satellites will be designed for towing, repairs, or refueling.

The Multimission Modular Spacecraft (MMS) would have had extended mission life capability by on-orbit servicing and refueling with monopropellant hydrazine [1930]. The larger MMS spacecraft, Mark II, would have required the transfer of 2265 kg (5000 lb) of hydrazine. Various tank configurations have been studied in an effort to identify existing tank designs that would utilize the space available in the Space Shuttle cargo bay most effectively. Some of the existing tanks would have had to be converted from MMH service to N<sub>2</sub>H<sub>4</sub> service to fit this application. Another basic consideration was if the tanks and their mounting were sturdy enough to withstand re-entry and landing shock in the STS payload bay if a rendezvous cannot be achieved or propellant transfer cannot be completed. Shuttles on extended duration missions could have carried OMS kits in the cargo bay and would have had the option to dump unused fuel prior to re-entry. Similar provisions would have had to be made if large hydrazine tanks for refueling missions had been flown in the cargo bay.

Refueling capability will be needed for monopropellant hydrazine as well as bipropellant NTO/MMH. Orbital fluid re-supply can significantly increase the cost-effectiveness and operational flexibility of satellites and orbiting platforms. For the sake of simplicity, the refueling of monopropellant hydrazine would be practiced first.

The Orbital Refueling System was an experiment flown on Shuttle Mission STS 41-G in October 1984. Liquid hydrazine fuel was transferred back and forth from one

spherical bladder tank to another using pressurized nitrogen as the driving force, which required EVA work of two astronauts making a fluid connection to a simulated Landsat interface [1931]. The system used existing flight-qualified STS APU tanks and a Fairchild quick disconnect [1932, 1933]. There was concern that excessively rapid (adiabatic) compression of the ullage in the receiving tank might cause exothermic decomposition of the hydrazine vapor if any hydrazine had inadvertently leaked across the diaphragm. Six back-and-forth transfers were achieved between the two diaphragm tanks without any incident. An analysis of the ullage heat transfer and comparison with actual flight data showed that the compression was much closer to an isothermal than an adiabatic process [1934, 1935].

Propellant transfer between tanks can be achieved by pumping or by pressurization. A particular concern is the venting of the propellant vapor-saturated pressurant gas from emptied tanks after a pressurized transfer is accomplished. The venting could result in undesirable reaction forces on the space station or the tanker vehicle. This can be minimized by using a pair of thrust-neutral nozzles. The corrosive propellant fumes contained in the vented pressurant gas might contaminate the solar panels or electronics. Special sorbent canisters have been considered for  $N_2O_4$  and MMH venting [1936]. In the case of hydrazine, the gas/vapor mix was passed through a catalyst bed identical to that used in hydrazine monopropellant thrusters. It would be ideal if the gas displaced by liquid in the tank being filled could be compressed and returned to the tank being drained (like vapor return hoses now seen at many Earth-based gas stations for automobiles to minimize air pollution). Analysis and modeling of no-vent transfers showed promising possibilities for larger satellites [1936]. Earlier experiments flown on STS used inert fluids and surface tension PMD tanks to study the behavior of liquids during transfer in surface tension PMD tanks. It would be easiest to transfer liquids only between diaphragm or bladder or piston tanks. However, diaphragm or bladder tanks are only available in small sizes. Eventually, the transfer of liquids between surface tension PMD tanks must be mastered so that transfers can be achieved between larger tanks.

Part of the propellant transfer operation in space involves the draining of propellant-filled hoses and line sections after the transfer is complete. On Earth's surface one would flush the lines with water and IPA, a luxury one does not have in space. Because manifold lines are not temperature-controlled and otherwise might freeze and rupture, it is best to empty them out at the end of the transfer operation. The complete evaporation of hydrazine from a manifold in vacuum is a very slow process, even with very carefully applied heat (possible by pointing that part of the spacecraft to the sun). It is difficult to verify how much hydrazine will remain after venting. It may not be acceptable to vent undecomposed hydrazine in the vicinity of delicate optics and electronic parts. If the hydrazine vapors must pass through a catalyst bed to decompose them to nitrogen, hydrogen, and ammonia, the process of emptying the lines will be even slower, and it is not known how complete the decomposition is at very low reactor operating pressures.

A computer model was developed to study the dynamics of propellant transfer during refueling of GRO satellite in orbit [1937]. The design goal was to transfer 387 kg hydrazine in less than 6 h, assuming that the tank still contained 169 kg residual hydrazine. It was concluded that the transfer would have to be extremely slow if helium was used as the pressurant due to adiabatic warming if one limits the maximum allowable ullage temperature to 338.7 K (150 °F) for safety reasons and fear of hydrazine vapor explosions. To be able to transfer the propellant within less than 6 h, nitrogen instead of helium was recommended as the pressurant gas. Nitrogen has a lower adiabatic coefficient  $\gamma = c_p/c_v$  than helium.

Military satellites are more vulnerable if they remain in the same predictable orbits all the time and would benefit from greater maneuverability and on-orbit propellant resupply. The US Defense Advanced Research Projects Agency (DARPA) conducted the Orbital Express mission, a two-satellite demonstration of propellant transfer launched in 2007. The system consisted of two spacecraft: the Autonomous Space Transport Robotic Operations (ASTRO) servicing satellite and a prototype modular next-generation serviceable satellite, NEXTSat [1938]. The ASTRO satellite successfully rendezvoused with and pumped hydrazine into its NEXTSat partner, the first in a series of increasingly challenging tests. In the first Orbital Express demonstration, ASTRO transferred just under 14 kg (32 lb) of hydrazine to the NEXTSat client, and then followed up by transferring an additional 8.6 kg (19 lb) of propellant to NEXTSat a day later. NEXTSat would then return propellant to ASTRO sometime later. After several back-and-forth propellant transfers, adding up to 15 transfer operations in the end, the 2 satellites separated, ASTRO vented its hydrazine propellant and was deactivated in July 2007 [1939–1941]. See also [1942].

Refueling of the SALYUT or MIR or International Space Station by unmanned PROGRESS tankers has already become a routine operation in the Russian space program.

## 7.6 Personnel Protection Equipment for Hydrazine Transfer Operations

Protective clothing to be worn by personnel in the vicinity of a pressurized hydrazine system depends on the type of operation to be performed [1943].

### 7.6.1 Gloves, Boots, and Aprons

One of the main concerns in selecting materials for gloves, boots, and aprons is the permeability in case of a liquid hydrazine spill on the protective equipment. In addition, there is concern over vapor permeability. Hydrazine permeation tests with various glove materials are summarized in the following section. Quite often one will want to reuse gloves after they have been contaminated with hydrazine. Effective decontamination methods should be tested before one decides to reuse those stained gloves. In

hypergolic propellant spill tests at NASA WSTF, it was determined that under adverse conditions the exterior of protective equipment may be exposed to vapor concentrations as high as 800 ppm MMH or 2%  $\text{N}_2\text{O}_4$ . These numbers were then used for permeation testing of different protective clothing materials [1944, 1945]. In these tests, four suit materials and one glove material were exposed to liquid splashes or heavy vapor concentrations of MMH or NTO under controlled conditions [1946]. The simple water wash and air dry sequence was not effective in removing residual propellants from the materials. Additional tests showed that an 8-h oven bake at 311 K (100 °F) or, even better, vacuum oven bake would more effectively remove MMH from the fabric. Arch Chemicals, a hydrazine manufacturer, recommends the use of Tychem<sup>®</sup> suits, aprons, and gloves. Tychem<sup>®</sup> is made by DuPont and is a PVC/polyvinylidene copolymer.

### 7.6.2 Hydrazine Permeation Tests

Commercially available protective gloves were tested for chemical resistance to H-70 hydrazine blend and subjectively evaluated for dexterity/flexibility [1947]. The gloves were considered alternatives to the bulky rocket fuel handler gloves used in maintenance and support of the F-16 EPU. A number of gloves (Edmont-Wilson 37-165; Surety 10-136R, 10-156R, and 10-166R; and Norton NSN: 8415-00-753-6550 through 6555) showed no detectable permeation of H-70 over a 6-h exposure at 293 K (20 °C) and were found suitable for one-time use during spill cleanup operations. These same gloves are considered adequate for repeated use during routine maintenance tasks; however, if liquid H-70 contact is experienced, the gloves should not be reused. Gloves should be decontaminated with 5% sodium hypochlorite bleach before disposal. Nitrile gloves of the same thickness, but from different manufacturers, gave breakthrough times of greater than 6 h versus less than 10 min. at 293 K (20 °C). Unfortunately, glove manufacturers change elastomers and manufacturing procedures based on economic conditions and market demand, and gloves evaluated 10 years ago may behave differently from ones bought today under the same brand name. It appears that the most important specification to ensure adequate chemical resistance from a glove is to have representative glove samples of various styles and construction from each manufacturer pass a chemical resistance test for the specific chemical of interest.

Several materials for gloves, boots, aprons, and splash shields were evaluated in permeation tests with hydrazine, UDMH, and IRFNA [1948–1950]. A group of 28 glove materials, 9 suit materials, and 3 other materials were tested for permeability to hydrazine, MMH or NTO following exposure to these propellants for 90 min. [1951, 1952]. Breakthrough times were determined and correlated with static permeation rates. Of the 28 glove materials, 9 had breakthrough times for hydrazine of less than 90 min. (2 of these shorter than 10 min.), 1 was marginal, 3 had barely detectable permeation, and 15 resisted permeation for at least 90 min. The comparable numbers for MMH were 19, 5, 1, 1, and 7 min. This indicated that it is more difficult to find good gloves for MMH protection than for hydrazine protection.

### 7.6.3 Full-Body Protection Suits

NASA developed the SCAPE suit as an alternative to industrially available personnel protection ensembles (PPEs). The NASA suits are fully encapsulated butyl-rubber-based suits and provide breathing air via either backpack or air hose [1916].

Eight different full-body protection suit materials were tested for permeability to hydrazine, MMH, or NTO during controlled exposure to these propellants. No hydrazine or MMH was detectable after 5 min of exposure [1952].

SCAPE suits used at NASA launch sites are made from a chlorobutyl coated Nomex fabric. The fabric and its coating are subjected to wear and tear, and its integrity needs to be monitored daily [1953]. In addition to corrosive chemicals from the outside, the inside of the suit is exposed to sweat and condensation [1954]. While every effort is made to keep astronauts in space suits during EVAs comfortable and safe, the design technology of SCAPE suits for ground-service crews lags behind. The amount of time a technician can safely spend suited up is typically less than 4 h, often shorter in the hot climates of Florida and Guyana.

Permeation resistance was determined by measuring the breakthrough time and time-averaged vapor transmission rate of MMH through two types of personal protective equipment [1955]. The two types of suits evaluated were the totally encapsulating ILC Dover Chemtursion Model 1212 chemical protective suit and the FabOhio PVC splash garment. The simulated exposure was (1) a saturated vapor exposure for 2 h or (2) a brief MMH splash followed by a 2-h saturated vapor exposure. Results showed that the totally encapsulating suit provided adequate protection at the new 10 ppb TLV-TWA. The permeation resistance of the PVC splash garment to MMH was poorer than any of the totally encapsulating suit materials tested because breakthrough occurred soon after initial vapor or splash exposure.

Several decontamination procedures for personal protective suit materials in use at NASA WSTF, including Chloropel (a chlorinated polyethylene [CPE]), were tested after the material was exposed to NTO or MMH [1956]. Each exposure sequence was followed by a simple room temperature water-wash decontamination sequence. Two versions of heated decontamination sequences were used: (1) a simple purged heated sequence and (2) a heated evacuation sequence. After the second water decontamination sequence these two versions of heated decontamination sequences were used to further reduce the concentration of residual fuel trapped in the material.

The permeation resistance of CPE used in chemical protective clothing for protection against hydrazine, MMH, or UDMH was determined by measuring breakthrough times and time-averaged vapor transmission rates using an ASTM F739 permeation cell [1957, 1958]. Two exposure scenarios were simulated: (1) a 2-h fuel vapor exposure and (2) a liquid fuel “splash” followed by a 2-h vapor exposure. To simulate internal suit pressure during operation, a positive differential pressure of 0.3 in. water (75 Pa) on the collection side of the permeation apparatus was used. Breakthrough was observed after exposure to liquid MMH and vapor or liquid UDMH. No breakthrough was observed after exposure to vapor or liquid hydrazine or vapor MMH.

Calculations showed that the maximum allowable permeation rates of hydrazine fuels through CPE were on the order of  $0.05$  to  $0.08 \text{ ng cm}^{-2} \text{ min}^{-1}$  for encapsulating suits with low breathing air flow rates (on the order of  $5 \text{ scfm}$  or  $140 \text{ L/min.}$ ) [1958].

The need to wear SCAPE suits and keep a second crew on standby ready to suit up if needed has a considerable impact on the cost and time required to fuel satellites and upper stages. There may be more economical and equally safe alternative ways to load propellants into satellites and upper stages [1959].

#### 7.6.4 Space Suits

Refueling of spacecraft in orbit may require EVA by astronauts to make connections of fuel hoses and operate valves. Propellant leaks may splash on the space suit and jeopardize the integrity of the fabric. Splashes on the visor of the space helmet may turn the plastic opaque and the astronaut may become disoriented if he/she cannot see the surroundings.

Fifteen different space suit materials in either the vertical or horizontal position were exposed to hydrazine spray from a spray nozzle in a vacuum chamber [1960]. Hydrazine, in the form of an approximately  $1.5\text{-mL}$  shot, was fed from a supply tank pressurized to  $207 \text{ kPa}$  ( $30 \text{ psig}$ ) through a spray nozzle. The samples were exposed to the splash for  $\sim 5 \text{ min}$  while their behavior was observed with a TV camera. Hydrazine splashed on the sample materials froze and evaporated (sublimed) only very slowly. The materials tested included Ortho fabric (a double layer of Teflon and Nomex used in the outermost layer of space suits), aluminized Mylar, Chemglaze A276 (white paint on helmet), buffed aluminum, RTV-630 silicone on aluminum or Dacron, Lexan polycarbonate (coated and uncoated), polysulfone (coated and uncoated, used for visor), Xenoy, composite of all suit materials, polyurethane glove internal bladder, and glove composite of all layers. Ortho fabric exhibited staining and soak-through as evidenced by staining on the reverse side of the fabric. Staining appeared on both Chemglaze A276 and RTV-630. Lexan polycarbonate crazed and became opaque, partially dissolved, and produced a gummy, sticky substance on the surface of the sample. Such a propellant splash on a helmet visor would cause astronauts to lose the view of their surroundings. Polysulfone in either a coated or uncoated condition did not suffer the same crazing as polycarbonate.

Splash evaporation tests of propellants spilled on space suit materials at three different initial sample temperatures showed that most propellant spills freeze almost immediately in vacuum [1785, 1786]. Hydrazine supercooled to  $355 \text{ K}$  and then froze to ice, which was near the triple-point temperature. The force needed to scrape frozen hydrazine from the material sample by scraping and the time needed to sublime frozen hydrazine under one solar flux (simulated with a heat lamp) was measured. MMH did not freeze but evaporated before much ice could form. MMH was the only propellant that visually damaged the suit material. Aluminized Mylar layers were found to be dissolved in the area where the propellant had impinged on the fabric. Supercooled

MMH dissolved the aluminized Mylar layers of the suit ensemble, and both hydrazine and MMH caused cracking in the polycarbonate helmet visor, but not in the helmet material alone.

### 7.6.5 Gas Masks

Air Force Occupational Safety and Health (AFOSH) Standard 48-137 (November 1, 1998) implements Occupational Safety and Health Administration (OSHA) Standard 29 CFR 1910.134, Respiratory Protection, for Air Force installations. That OSHA standard provides guidelines in the safe use of gas masks and determines when supplied air respirators or self-contained breathing apparatus should be used. It is interesting to note that AFOSH Standard 48-8 on page 35 of Attachment 8 states that “The end-of-life indicator on the rocket propellant gas mask does not adequately respond to hydrazine. The maximum use time is 8 hours; supervisors will enforce procedures to replace the canisters before the canisters have been exposed for 8 hours, without regard to whether the mask is being worn.”

The MSA Rocket Propellant Mask 92372GM-SSW canister and, to a lesser extent, the M9 mask with the M11A1 charcoal canister provided effective protection against hydrazine and UDMH vapors when tested under actual field conditions [711, 712]. Whereas outside concentrations were as high as 2 ppm hydrazine or 3 ppm UDMH, no hydrazines could be detected inside the M9 mask. Only during one test with 4.6 ppm UDMH outside was a trace (0.03 ppm) of UDMH detected inside the mask. This isolated incident was blamed on an inadequate mask-to-face seal. Other cartridges for removing hydrazine from air consisted of a two-layer bed, one a charcoal, silica gel, alumina, or molecular sieve sorbent and the other a solid oxidizer on a solid support [1961].

## 7.7 Detection of Hydrazine Leaks

A space vacuum leak-detection concept was able to generate distinctive leak characteristic temperature curves by evaporative cooling for each leak rate assuming hydrazine was leaking into the APU compartment of the Space Shuttle [1962]. Although exact quantification of a leak would not be possible, qualitative determination of the leak amount and location appeared achievable. The tests demonstrated potential for use of an evaporative cooling sensor in a vacuum environment where conventional leak sensors do not work effectively. A leak-detection concept was based on evaporative cooling as a result of an instantaneous reduction of the fluid surface pressure when an on-orbit leak occurs. The effect of the surface evaporative cooling produces a characteristic temperature drop as a result of heat removal by conduction.

## 7.8 Controlled Spill Tests with Hydrazine and Hydrazine Blends

Hydrazine leaking into vacuum is going to cool by evaporation down to the triple-point temperature, and liquid droplets in a hydrazine spray will soon freeze and turn into hydrazine snow. This condition was simulated by spraying liquid hydrazine into a vacuum chamber with visual (video camera) observation [1963]. Hydrazine leaking into vacuum will quickly freeze and assume triple-point conditions. The rate of hydrazine sublimation may be very low, depending on available sources of heat. Hydrazine spilled on a space suit during EVA activities may not evaporate quickly enough and could be dragged into the space station after the astronauts re-enter the air lock [111].

### 7.8.1 Spill Decontamination and Disposal

Despite all the precautions taken in planning and conducting storage and transfer of hydrazines, occasional spills may occur. Transfer personnel should be well trained in the containment and neutralization of hydrazine spills. Several mathematical models have been developed for spill hazard assessment by hazardous materials response teams. These will be discussed in the following paragraph.

Hazardous material (HazMat) teams are specifically trained on how to deal with propellant spills, either off site or on site. A computer program can assess the type of response needed to bring the situation under control, depending on the type and quantity of propellant spilled, the proximity to populated areas, and geographical conditions [1964].

### 7.8.2 Hydrazine Spill Hazard Evaluation and Mitigation

Hazardous chemical spill response training has become an important part of the transportation industry and local accident response teams.

### 7.8.3 Atmospheric Dispersion Models of Hydrazine Vapor (without Reaction)

A vapor cloud caused by either the vaporization or reaction of hydrazine, UDMH, MMH, and NTO, as it was used on the APOLLO spacecraft, was analyzed to determine the generation and concentration of toxic products and the safe toxic distances in case of a spill [1965]. It was predicted that the process of vaporization of propellant without reaction would create the largest quantity of toxic products. Assuming that the total quantity of fuel or oxidizer aboard the APOLLO spacecraft would be spilled in sand and vaporized during unfavorable atmospheric conditions, it would have resulted in a maximum safe toxic distance of 5.5 km (3.4 miles). This safe toxic distance was considered to be the worst case because the cooling effects of vaporization tend to reduce the actual rate of vaporization. Reaction of hydrazine, UDMH, and MMH with NTO will produce a smaller quantity of toxic product, thereby reducing the toxicity hazard.

These hot products, when formed, being above ambient temperature and buoyant, will rise and expand, creating a faster rate of product dispersion and dilution.

Evaporation studies with simulated 10 g hydrazine and H-70 spills in 9-cm-diameter Petri dishes showed that although all samples lost hydrazine, some gained weight by moisture and carbon dioxide absorption from the air [723, 1966, 1967]. With pure hydrazine, 6–9 g evaporated within 3 h under Florida outdoor conditions. Similar loss rates (7.6 g/3 h) were obtained in a hood in a laboratory with an air speed of 0.6 m/s at 294 K. The evaporation rate slowed down significantly after 20 h. The remaining hydrazine was very viscous from carbazate formation. In a separate test where pure CO<sub>2</sub> was bubbled through H-70 fuel to constant weight, 50 g of H-70 fuel absorbed 30 g of CO<sub>2</sub>, and carbazate precipitated. Carbon dioxide suppressed hydrazine evaporation. No hydrazine evaporated when CO<sub>2</sub> was passed over the sample, and CO<sub>2</sub>-free nitrogen caused more rapid evaporation than ambient air.

Fuel evaporation rates were determined under controlled laboratory conditions in glass dishes of various sizes (11.6, 63.6, and 177 cm<sup>2</sup>) [1968]. Air velocity over the evaporating fuel was 132 cm/s, and the temperature was controlled to within  $\pm 2^\circ\text{C}$ . The evaporation rates in a 177-cm<sup>2</sup> dish were 0.49 mg cm<sup>-2</sup> min.<sup>-1</sup> for hydrazine, 1.7 mg cm<sup>-2</sup> min.<sup>-1</sup> for MMH, and 13 mg cm<sup>-2</sup> min.<sup>-1</sup> for UDMH.

The determination of a hazard corridor following a hydrazine spill involves two separate calculations [1969, 1970]. First, an estimate of the evaporation rate (source strength) must be made [1971]. Then an atmospheric diffusion model must be employed to predict the downwind distance required to dilute that source strength to a concentration that is considered tolerable. Sample calculations for a 20-m<sup>3</sup> trailer spill on a 36-m<sup>2</sup> area assumed a short-term public limit (STPL) of 7 mg/m<sup>3</sup>. For a spill depth of 2.5 cm and a wind speed of 3 m/s, the hazard corridor would extend 360 m downwind. Computer models are available that will predict the concentration-time profile of the vapor plume as a function of 10 input parameters. Constants that are part of the equations have been determined for hydrazine, H-70, MMH, and UDMH. A 30-min public exposure limit (PEL) for hydrazine of 20 ppm (26 mg/m<sup>3</sup>) was assumed for these calculations.

A computerized evaporation algorithm predicts the rate of evaporation as a function of soil temperature, solar insolation, air temperature, wind velocity, and spill dimension [1972, 1973]. A single-source Gaussian dispersion formula calculates the downwind, ground-level centerline concentration based on dispersion coefficients available in current EPA models. The dispersion algorithm also calculates the crosswind dimension of a hazard corridor in which the STPL is exceeded. The model allows for the absorption of water and carbon dioxide from the atmosphere into the liquid puddle, which would slow the rate of evaporation. It will also provide a calculation of the amount of water required to dilute a spill below hazardous concentrations. In some instances, such as in the massive TITAN III or TITAN IV launch failures, the toxic vapor/toxic aerosol plume is a mixture of solid propellant combustion products containing hydrogen chloride and aluminum oxide with

the unreacted NTO and hydrazines from the liquid stages. Modeling atmospheric diffusion of plumes of this nature is a very complex task [1974, 1975]. Some reactions continue to occur on the aluminum oxide particles while they disperse and descend.

Sample calculations for 200-L (drum), 20000-L (trailer), and 36000-L (rail car)  $N_2H_4$ , MMH, and UDMH spills at three different ambient temperatures (273, 288, and 303 K) showed that in the case of a 36000-L spill, the hazard corridor would reach 480 m downwind for hydrazine, 1380 m for MMH, and 680 m for UDMH. The rate of evaporation from a liquid pool is

$$\dot{m} = k_m \frac{P_v M A}{R T_p}$$

where  $\dot{m}$  is the mass flow (kg/h),  $k_m$  the mass transfer coefficient (m/h),  $P_v$  the vapor pressure (kPa),  $A$  the spill area ( $m^2$ ),  $R$  the universal gas constant ( $8.314 \text{ kPa m}^3 \text{ kg}^{-1} \text{ mol}^{-1} \text{ K}^{-1}$ ),  $M$  the molecular weight, and  $T_p$  the pool temperature of pool (K). Allowances were made for composition changes in the remaining pool due to preferential evaporation of a more volatile constituent of a mixture, absorption of water from the atmosphere, and both absorption of and reaction with carbon dioxide from the atmosphere. The evaporation rates of UDMH and MMH for similar meteorological and spill conditions are 11 and 3 times that of hydrazine, respectively. Comparison of predicted and experimentally observed evaporation rates showed good agreement for the first hour of the experiment.

None of the atmospheric dispersion models published so far accounts for the decay of hydrazine vapor as a result of autoxidation or photolysis. These need to be factored in because the half-life of hydrazine vapors may be of the same order as the time required to diffuse from the location of the source to the area of concern.

An empirical diffusion equation was used to calculate the downwind hazard distance in case of accidental spills of toxic chemicals [1976]. The width of the toxic corridor, specified in angular degrees centered along the mean wind direction, was based upon the variability of the wind direction. Estimating toxic corridor evacuation areas on the scene of an accident was facilitated through four different methods using tables, monograms, or a programmable calculator and procedures for determining meteorological inputs and evaporation source strength, as well as other items. See also [1977].

The Atmospheric Release Advisory Capability (ARAC) suite of three-dimensional transport and diffusion codes MATHEW/ADPIC was used to assess the consequences of severe, hypothetical accident scenarios [1978]. One set of calculations developed the integrated dose and surface deposition patterns for a non-nuclear, high-explosive detonation and dispersal of material. A second set of calculations depicted the time-integrated dose and instantaneous concentration patterns for a substantial, continuous leak of the missile oxidizer converted to nitrogen dioxide ( $NO_2$ ). The downwind areas affected and some of the implications for emergency response management can be predicted by this model.

The launch abort problem, for instance for a TITAN III or TITAN IV launch mishap, is especially difficult because there are separate initial clouds of fuel and oxidizer, with regions of mixing between them. An attempt was made to deal with this problem using a so-called multi-bin approach, which treated the fuel and oxidizer and an interface as separate bins but kept the computation tractable [1979]. The computer program was based on SURFACE CHEMKIN, a standard chemical kinetic sub-routine package [1980]. The model results showed that the outcome was highly dependent on initial conditions. For instance, a likely scenario for a Titan IV accident will result in 24% of the initial oxidizer remaining, of which at least half is transformed into nitric acid, and 2% of the initial fuel remaining.

Concentrations and dispersion of toxic vapor clouds formed by non-burning propellant that splashed onto the ground and evaporated and diffused after a launch failure of a liquid propellant launch vehicle can be predicted by an analytical model, depending on the launch site environment and weather conditions [1981, 1982].

Predictions from a theoretical model of liquid rocket propellant vaporization rate for the source strength were compared to experimental results of the evaporation rate of spilled propellants in a natural environment [1983].

#### 7.8.4 Spill Immobilization

During the testing of materials to permanently destroy spilled hydrazines, various concepts were tested that would temporarily immobilize the hydrazine spill until more permanent corrective action could be taken. Such immobilization methods include gelling, sponges, wipes, and foaming. Dry powder gelling agents were tested as treatment for 96%  $N_2H_4$  by dumping 5 g of solid onto 5 g of fuel [1984]. The most effective solid was a gellant, CMC Type 7HS cellulose gum, that permitted only 0.03% of the spill to escape overhead as vapors. The second best was a hydroxyethyl cellulose gellant. Unfortunately, gelled hydrazine is more difficult to neutralize later than a clear aqueous solution. Another method to minimize hydrazine evaporation until more permanent control methods can be instituted is to cover the hydrazine up with high-expansion aqueous foam for firefighting. Three types of foam were tested, and all three were equally effective as a vaporization barrier. In another study, several types of foaming agents were tested to reduce the evaporation of hydrazine and keep the hydrazine concentration in the vicinity of the spill below 0.5 ppm [1985]. The following foaming agents were tested: aqueous film forming foam (AFFF), National AeroFoam protein foam 6% regular, National XL 6% fluoroprotein foam, National Aero-O-Water 6% fluorocarbon foam, and MSA Ultrafoam V surfactant. AFFF can make high-expansion foam, but it drains very fast. Protein base foams were not very compatible with hydrazine. A fluorocarbon-based polar solvent foam made by 3M was compatible with hydrazine and provided good protection. Ideally, a foaming agent was sought that would leave a polymer skin on the liquid puddle even after the foam had collapsed. An acrylic modified foam that gels when it comes in contact with ammonia (recommended as treatment of liquid ammonia spills) was also tested for its efficacy against

hydrazine evaporation. A Type 95 foam reduced hydrazine vapor concentration above the spill to a few ppm, but its supplier was not identified.

Passing carbon dioxide snow (e.g., from a CO<sub>2</sub> fire extinguisher) over hydrazine spills will reduce the rate of hydrazine evaporation. Dumping liquid nitrogen or dry ice or water ice on the spill was another method tested to reduce hydrazine evaporation and to gain time until other control methods could be implemented [1986].

Laboratory screening tests were conducted to evaluate a variety of foam systems for hydrazine and/or N<sub>2</sub>O<sub>4</sub> vapor mitigation and minimizing the release of toxic hypergolic propellant vapors from spills [1987]. Two of the systems demonstrated the feasibility of maintaining a cover atop the propellant spill over an extended time by periodic reapplications of fresh foam. The vapor suppressant properties of these foam systems had been sufficiently demonstrated so that they could be incorporated into the arsenal of emergency response equipment for hypergolic propellant spills. The evaporation of hydrazine (and ammonia) from hydrazine spills can be retarded by adding a surface-active agent (surfactant) to the flushing water. Additives that have been patented for this purpose are long-chain amines of the general formula RNH<sub>2</sub>, where R is an alkyl group containing at least 12 carbon atoms and generally in the range of 12–26 carbon atoms [1988]. The mechanism by which the surfactant inhibits the volatilization of ammonia or hydrazine is not completely understood. Absorbent pads or pillows have been evaluated that can be applied to spills as a first step measure [1989].

#### 7.8.5 Spill Decontamination

Chemicals used to decontaminate hydrazine in water are generally oxidizers that permanently destroy and oxidize hydrazine to nitrogen and water, hopefully without the formation of nitrogen oxides or hydrogen azide as byproducts. Methods discussed here for spill decontamination that must be portable (so the decontamination unit can quickly move to the location of the spill) may work equally well in stationary installations but may not be the most economical solution to a stationary, continuous disposal problem. The same chemical may serve both applications, or different chemicals would be used for accidental (rarely occurring) spills and continuous, planned disposal of hydrazine. Olin Chemicals, once a major hydrazine manufacturer, recommended an aqueous solution of calcium hypochlorite (Olin trade name HTH<sup>®</sup>) for the decontamination of hydrazine spills. In the as-purchased form, Olin HTH is a white granular powder that is easily stored in sealed containers and must be dissolved in water prior to application. HTH is mainly used for swimming-pool disinfection and is generally available from swimming pool supply stores. Liquid decontaminants such as chlorine bleach (sodium hypochlorite, NaOCl, household bleach) or hydrogen peroxide, H<sub>2</sub>O<sub>2</sub>, are not as safe to store and may decompose during storage. During the disposal of hydrazine itself with NaOCl or H<sub>2</sub>O<sub>2</sub>, none of the toxic *N*-chloroamines or nitrosamines form that are occasionally observed with MMH or UDMH oxidation reac-

tions. With all decontaminating agents acting on any of the three hydrazines, nitrogen will be evolved that may lead to the buildup of high pressure in a closed system. Thus, provisions for venting gases and aerosol mists must be made while decontamination is in progress. The gas may also carry away some unreacted hydrazine vapor and nose-irritating mists. Reaction of hydrazine with hydrogen peroxide under incorrect pH conditions may form hydrazoic acid (hydrogen azide), which is even more poisonous and explosive than hydrazine itself.

None of the hydrazine spill decontamination agents can be applied to undiluted spills of anhydrous hydrazine or MMH or UDMH directly. It is important to dissolve HTH in water first, forming a dilute solution; otherwise the spilled hydrazine may ignite and aggravate the problem at hand. As a general rule, the spill must be diluted with water first and flushed into a holding tank. Decontamination can then take place in the holding tank. If any of the decontaminating agents, such as concentrated sodium hypochlorite solution or HTH powder, is poured directly on undiluted concentrated hydrazines, the heat of reaction will most likely lead to ignition of the spill.

Polypropylene felt wipes were evaluated and are now recommended by NASA and USAF for cleaning up small hydrazine or H-70 spills on smooth surfaces. The felt is less efficient in mopping up spills on porous surfaces, such as concrete. The procedure there would be to mop up as much of the spill as possible, dilute with water, and then treat the wet spot in the concrete pad with hypochlorite (diluted household bleach or HTH).

During a series of hazard classification tests, both above-ground and in-silo configuration spill tests were undertaken with hydrazine, Aerozine-50, and NTO for the TITAN II program, with up to 815 kg (1800 lb) of propellants spilled at a time [1990, 1991]. This was done in order to assess the potential hazard during cleanup. A total of 92 small-scale tests were performed using propellant quantities not exceeding 2.26 kg (5 lb) in weight. Propellant weights used on the nine large-scale tests ranged from 61 to 815 kg (135 to 1800 lb) of total propellant.

In one of the first thorough studies on hydrazine (and UDMH) spill decontamination, 94 different chemicals were reviewed for their suitability as spill control agents [1984]. One percent sodium hypochlorite solution was most efficient in minimizing hydrazine vapor emissions while the neutralization was in progress. One percent potassium permanganate solution reacted faster than hypochlorite but allowed more unreacted hydrazine to escape during neutralization. Eight solids were tested as decontaminants for 96%  $N_2H_4$  by dumping 5 g of solid onto 5 g of fuel. In the case of dry calcium hypochlorite, the mixture promptly ignited.

Spill decontamination methods were developed for hydrazine-based propellant mixtures such as MHF-3, MHF-5, alumizine, and beryllizine [1992]. Spill neutralization and disposal of the gelled, metallized propellants is more difficult because of the presence of metal powders and gelling agents. On the other hand, spills of gelled propellants remain localized, which is a substantial safety advantage of gelled propellants. Alumizine may exotherm if it is diluted with insufficient water and the hydro-

gen gas evolved may become a secondary explosion hazard. Neutralizing agents (hydrogen peroxide, sodium hypochlorite, potassium permanganate, potassium dichromate) were applied as 5% solutions and with a 50:1 mass ratio. The gel of alumizine was broken down by several neutralizing agents, which facilitated further cleanup. Three percent NaOCl solution was judged too reactive since it would spatter reactants around. Three percent  $\text{H}_2\text{O}_2$  solution was the preferred agent for the neutralization of metallized propellants, since it was the only agent that showed satisfactory neutralization effectiveness with no undesirable side reactions.

As an alternative to hypochlorite, copper-catalyzed hydrogen peroxide has also been evaluated, but the report fails to mention the potential of hydrogen azide and copper(II) azide formation under these conditions if the pH is not correctly adjusted. The use of calcium hypochlorite (e.g., HTH) is the most economical way to neutralize hydrazine spills, water runoff from such spills, and water extracts from felt squares used to mop up such spills, but the remaining calcium salts are sometimes hard to remove from surfaces, and a lime slush may settle at the bottom of the neutralization vessel. Hypochlorite should be added (5 kg HTH dissolved in water for every liter of H-70 = 42 lb/gal or 100 volumes of 5% household chlorine bleach for each volume of H-70 spilled) until an excess of free hypochlorite can be detected with 0.1% orthotolidine in 8% HCl aqueous solution indicator. A catch treatment container of approximately 30-gal capacity should be on hand to treat the contents of one F-16 EPU tank holding 6.5 gal of H-70 mix.

Solid sorbents/neutralizing agents would be preferred over liquid reagents because they do not constitute a spill/leak hazard of their own. Various transition metal oxides and sulfates were tested at very low pressures for the speed of reaction with hydrazine vapor (their so-called reducibility) using changes in the oxide-oxygen XPS peak as an indicator. Hydrazine vapors adsorb reversibly on silica-alumina evaluated as a sorbent [1993]. Copper(II) oxide was the most reactive and iron(III) oxide was the least reactive of nine oxides tested. Copper(II) oxide becomes reduced to metallic copper in the process. The copper(II) oxide is preferably deposited on an inert porous clay material to prevent excessively fast and hot reactions [1994]. Some of these agents may cause spilled hydrazine to ignite, which would make the situation even worse. If the hydrazine spill is diluted below its flash point, the agent may react only very slowly.

One of the more promising spill control materials was 10.5% copper(II) oxide supported on silica or Microcell-E foam. NASA WSTF evaluated these two materials by applying them to a simulated spill consisting of 1 L of 1% hydrazine solution [1995, 1996]. The materials were applied as loose powders or contained in a polypropylene fabric pillow. The temperature increased by up to 25 °C during the neutralization reaction, which did not aggravate the disposal hazard. The hydrazine decomposition reaction reached 75% completion within 3–15 h for all spill-control materials. The general reaction stoichiometry was 2 mols copper(II) oxide to 1 mol hydrazine.

An acetate-acetic acid buffer with a gelling agent was tested as a spill control medium against small spills of Aerozine-50 or NTO [1997]. See also [1998–2002].

USAF Armstrong Laboratories (Brooks AFB) have evaluated the *in situ* biological remediation of hydrazine spills in the soil using gel-encapsulated enzymes. This would be a very slow process.

#### **7.8.6 Accidental Hydrazine (Hydrate) Spill Case Histories**

There was an isolated incident caused by derailment of a train, causing a spill of hydrazine hydrate from 16 punctured steel drums in a railroad accident near Sea Cliff, CA, on July 28, 1991. No major environmental damage occurred since the spill site was quickly surrounded by a dam and leaked hydrazine hydrate was destroyed with hypochlorite.

In July 1992, three people suffered minor injuries when a box containing anhydrous hydrazine leaked in the Air France/Continental Airlines cargo area at O'Hare International Airport.

In November 2003, a leaking tractor trailer released nearly 20 gal hydrazine hydrate onto Interstate 190 near West Boylston, MA, causing a 4-mile stretch of the southbound lanes to be closed for about 9 h. As the truck was pulling into the breakdown lane, it shot out a thick cloud of chemical that covered all the southbound lanes. The truck was transporting 43600 pounds of hydrazine hydrate. The leak was probably caused by a pressure release valve that functions when the inside pressure of a tank becomes too high.

### **7.9 Disposal of Hydrazine**

Before one undertakes the task of disposing of surplus hydrazine and hydrazine wastes, one should investigate salvage and reuse of the waste hydrazine. There may be methods of reprocessing contaminated hydrazine into a useful product, the manufacturer may agree to take aged and out-of-spec product back for reprocessing, or one may find other applications for the waste hydrazine. For instance, in a large industrial operation that also has chrome plating finishing operations and chromate-containing wastewaters, the use of hydrazine to convert hazardous chromate to the precipitable chromium(III) would be a way to kill two birds with one stone, so to speak. In other instances, precipitation of hydrazine from hydrazine waste solutions as sparsely soluble hydrazinium(2+) sulfate may lead to a saleable solid waste product that may find other uses. Hydrazinium(2+) sulfate is easily stored as a solid and does not have a noticeable vapor pressure.

### **7.10 Disposal of Concentrated Hydrazine**

Hydrazines that must be disposed of for some reason (contamination, surplus, demilitarization) can be destroyed by burning, autoxidation, or chemical oxidation. The de-

struction of hydrazine itself is the easiest task compared to the effort required for the disposal of methylhydrazines. Several of the methods described here for hydrazine may work equally well on methylhydrazines. Some of the methods for the disposal and decontamination of hydrazine(s) will be discussed here and again in the accompanying chapters on alkylhydrazines.

### 7.10.1 Open-Pan Burning

One quick method of disposing of surplus hydrazine, although frowned on by some regulatory agencies, is to burn it in open pans. Because the only products of combustion are nitrogen and water, this should be an environmentally benign and ecologically acceptable method of disposal. For instance, 25 mL anhydrous hydrazine in a 18 × 28-cm steel pan burned and disappeared within 17 s [2003]. Only 0.3–0.7% of the total hydrazine was found unburned when the pan was rinsed with water after the fire. Neat hydrazine burned rapidly, leaving little residual hydrazine, but ignition of aqueous solutions became progressively more difficult as the water concentration increased. Ambient air concentration during the fire ranged from less than 0.1 to 11.5 mg/m<sup>3</sup>. While anhydrous hydrazine burned quite readily, disposal of the 70/30 hydrazine/water mixture by burning did not go as smoothly. Three to eight percent of the hydrazine was left unburned, and the ambient hydrazine concentration was up to 75 mg/m<sup>3</sup>. The mixture burned much more slowly than did 100% N<sub>2</sub>H<sub>4</sub>, and it took 88 s to consume 25 mL fuel.

Hydrazine solutions containing less than 50% by weight N<sub>2</sub>H<sub>4</sub> could not be burned in open pans unless some supplementary fuel was added [1966]. Adding 1:1 volume parts of methanol to an otherwise incombustible 50% N<sub>2</sub>H<sub>4</sub>/50% H<sub>2</sub>O solution rendered the mixture again flammable, and it burned with 92% efficiency (8% of the hydrazine was left unburned in the pan). Adding JP-4 instead of methanol achieved even more efficient hydrazine destruction; only 2% of the hydrazine was left unburnt after burning a 1:1 (by volume) JP-4/50% N<sub>2</sub>H<sub>4</sub> mixture. This method is not suitable for dilute solutions but is restricted to concentrated hydrazines.

### 7.10.2 Incinerator Burning

The two-stage combustion of hypergolic rocket propellants (N<sub>2</sub>O<sub>4</sub> and the three hydrazine fuels) in an optimized burner was expected to lead to a minimum discharge of NO<sub>x</sub> into the environment [2004]. The first stage of combustion allowed the fuel or oxidizer to react in a respectively lean or rich flame, yielding a mixture of products including the inevitable NO<sub>x</sub>. The second stage of combustion was supposed to achieve the reduction of NO<sub>x</sub> as the result of addition of NH<sub>3</sub> or H<sub>2</sub> (Thermal DeNO<sub>x</sub>) or cyanuric acid. The objective was to understand and control the turbulent combustion of these propellants through the application of fluid dynamics and kinetics modeling, in conjunction with optical and mass-spectrometer-based flame diagnostics.

Several incinerator burner designs were qualified and certified for the destruction of chemical warfare agents, and they should work just as well for the less toxic and

more reactive hydrazines. A toxic waste burner has been built and evaluated for burning of hydrazine or UDMH with a hot gas (pre-burner) and additional air [2005]. The goal was to reduce  $\text{NO}_x$  emission in the exhaust gases down to less than 165 ppm. Initially, hydrazine and UDMH were tested in an existing air-cooled liquid incinerator with natural gas used for ignition (and in some cases necessary to sustain combustion). Air was used as the oxidizer. Hydrazine and UDMH could be destroyed by incineration down to a level below 2 ppm residual hydrazines with  $\text{NO}_x$  emissions in the discharged gas in concentrations well below 165 ppm. Incinerator dwell times were on the order of 0.1 s.

Another burner developed for the disposal of liquid propellants disposed of over 453 kg/h (1000 lb<sub>m</sub>/h) of liquid propellants including hydrazine by burning it in air to produce exhaust gases in the 977 K (1300 °F) range, which contained only acceptably low levels of nitrogen oxides [2006].

## 7.11 Entrapment and Disposal of Hydrazine Vapors

### 7.11.1 Hydrazine Vapor Scrubbers for Absorption from Vented Pressurant Gases

Several methods have been considered for the disposal of hydrazine vapors such as those emanating from tanks (stationary tanks, tank cars, drums) to be filled with hydrazines or those from pressurized tanks that are vented to ambient pressure after the completion of transfer operations. Because hydrazine concentration and flow rate can vary over a wide range, it is difficult to design a system that suits all conditions equally well.

In most cases, for stationary test operations on the ground, the hydrazine vapors are passed through a counter-current liquid scrubber. This does not actually solve the pollution problem; it only converts it from an air pollution problem to a water pollution problem. The advantage of the liquid wastes generated from a scrubber is that they can be accumulated in a holding pond and then treated at a slower rate of reaction than would be necessary for the rapidly venting gases. As a first approach, one might use just plain water (no acid) as the scrubber liquid. In this case, the efficiency of the scrubber is limited by the volatility of hydrazine(s) from dilute aqueous solutions. The vapor-liquid equilibrium is governed by Henry's law. The Henry's law constants (Section 2.1.9.4) must be known to design a scrubber and determine how many stages are required to achieve satisfactory absorption of hydrazine vapors contained in the pressurant gas of propellant tanks [2007]. These constants were determined for aqueous solutions containing 0.1 to 1% of hydrazine or MMH in buffered (pH = 7) and unbuffered solutions. The effect of salinity on hydrazine volatility was also tested. Instead of using just plain water as the scrubber liquid, for all practical purposes it is more efficient to use acidic solutions as scrubber liquids.

During the early 1980s NASA KSC initially used bubble-cap scrubbers 0.5 m wide and 6 m high with 18 plates to absorb propellant vapors from gases vented from hydrazine servicing equipment into recirculating water [2008]. Each plate carried 16

bubble caps, typical for chemical industry absorption towers. The propellant vapor was washed with water, and the hydrazine-laden water was subsequently treated with hypochlorite in a separate installation. The scrubber was tested with gases containing 100 ppm hydrazine, 150 ppm MMH or 45000 ppm MMH, or 110000 ppm UDMH, and the effectiveness of the scrubber was verified by sampling the off-gas with Dräger tubes. The scrubber system was later converted to operate on citric acid solutions instead of plain water. The bubble cap scrubber was later replaced by a portable, skid-mounted  $1.8 \times 1.8 \times 3$ -m system containing four vertical columns packed with Raschig rings. The four columns drained by gravity into a common 2800-L scrubber liquor tank located beneath the towers. The gas flowed through each of the four towers in series.

Hypergolic fuels and oxidizer pressurant gases were vented during fueling and de-servicing Space Shuttle and other spacecraft and cleansed of toxic propellant vapors before allowed to be vented to the environment. The scrubbers are not 100% efficient and traces of propellant vapors pass through the apparatus. Scrubber emissions are difficult to measure due to the intermittent purge flow and due to the presence of suspended scrubber liquor droplets. An alternative method for emissions monitoring and estimating was introduced [2009, 2010]. It was suggested that emissions could be determined from field scrubbers without the direct measurement of vent flow rates and escaped hypergol vapor concentrations. This alternative approach was based on the scrubber efficiency, which was previously measured during normal steady-state operations, and on the accumulated weight of hypergol captured in the scrubber liquor, which is part of the routine monitoring data of scrubber liquors. The emissions from scrubbers can be calculated by measuring the buildup of hypergol propellant in the liquor, and then using the appropriate efficiency to calculate the fugitive emissions. An estimate of the total emissions from 16 scrubbers at NASA KSC over a period of 3 years indicated that only 0.3 kg/year of fuel (MMH and hydrazine) and 234 kg/year of nitrogen dioxide were emitted [2011, 2012].

$\alpha$ -Ketoglutaric acid [= 2-ketoglutaric acid, AKGA,  $\text{HOOCCH}_2\text{CH}_2\text{C(O)COOH}$ ], a water-soluble solid, has been proposed for hydrazine or MMH vapor absorption from air or for the decontamination of wastewater from rinsing hydrazine- or MMH-contaminated rocket propulsion systems [2013–2015]. The reaction of  $\alpha$ -ketoglutaric acid with hydrazine or MMH forms a non-volatile, non-toxic (less toxic) heterocyclic pyridazine compound.

Alpha-ketoglutaric acid and ethyl acetoacetate were examined as potential alternatives to the hydrazine-family fuel vapor scrubber neutralization techniques used at

NASA KSC. Both reagents react with hydrazine-family fuels to form non-volatile hydrazone derivatives. Each of these reactions was characterized with an emphasis on applicability for implementation in so-called real-world processing scenarios such as the decontamination of flight hardware and ground support equipment or as drop-in replacements for the current scrubber liquor used in typical KSC four-tower vapor scrubbers. Preliminary testing was performed by the reaction of reactant solutions with hydrazine fuels in both liquid and vapor phases. A one-tenth-scale scrubber was built to demonstrate this technology. Specific properties examined included reaction efficiency and comparison to the current citric acid scrubber reagent, product solubility, and undesirable precipitate saturation points.

$\alpha$ -Ketoglutaric acid adsorbed onto a solid silica-based substrate was examined as a vapor scrubber medium, a potential alternative to the hydrazine-family hypergolic fuel absorption/neutralization techniques currently used at NASA/KSC [2016]. Hydrazine-absorbent fabric or metal screen saturated with solutions of dicarbonyl compounds like  $\alpha$ -ketoglutaric acid or acetylacetone or ethyl acetylacetate can be used to absorb hydrazine vapors from air or can be used as a sorbent pad to immobilize small hydrazine spills [2017].

A critical review of patent claims and preliminary laboratory test results with  $\alpha$ -ketoglutaric acid for hydrazine or MMH vapor absorption or decontamination of hydrazine- or MMH-contaminated rocket propulsion systems concluded that the uncertainties of the completeness of the reaction and lack of complete identification of all reaction products prevented the practical application of this chemical under real-life rocket launch site GSE conditions [2018]. When reacting 0.73-M AKGA solutions in benchtop lab tests, a solid formed with hydrazine but not with MMH. In more dilute 0.2-M AKGA solutions, no precipitate formed with either hydrazine or MMH. Another di-keto compound tested in hydrazine or MMH scrubber liquids was ethyl acetoacetate  $\text{H}_3\text{C}-\text{C}(\text{O})-\text{CH}_2-\text{C}(\text{O})-\text{O}-\text{CH}_2\text{CH}_3$ , but its reaction with hydrazine or MMH produced a gummy, sticky substance (a carbinolamine intermediate converting to 3-methylpyrazol-5-one) that clung to the walls and was difficult to remove.

NMR reaction kinetic studies verified that the  $\text{N}_2\text{H}_4/\text{AKGA}$  reaction proceeds at a rate sufficient for industrial wastewater treatment uses even in the presence of other compounds found in industrial waste streams [2019]. Toxicity studies determined that the products of the reactions were not toxic to crustaceans and fish. Therefore, waste streams produced from these reactions can be metered into a municipal wastewater facility for final disposal. NMR identified byproducts produced by the reaction of  $\text{N}_2\text{H}_4/\text{AKGA}$  and MMH/AKGA as being only 6-oxo-1,4,5,6-tetrahydro-pyridazine-3-carboxylic acid (PCA) and 1-methyl-6-oxo-1,4,5,6-tetrahydro-pyridazine-3-carboxylic acid (mPCA), respectively. Biodegradation NMR studies with  $^{13}\text{C}$ -labeled PCA and mPCA were made to compare the labeled material before and after exposure to microbial populations obtained from a wastewater treatment plant. PCA (up to 5000 ppm) degraded almost completely forming  $\text{CO}_2$ , but mPCA did not show significant biodegradation in a period of 28 d.

Rainwater collecting on the pad surrounding a scrubber may contain some residual hydrazine and must be treated as hazardous waste if the hydrazine concentration is above 200 ppb [2020]. Most likely the hydrazine would slowly deteriorate on its own under the influence of air and sunshine.

Because of the intense flashback hazard, it is not easy to dispose of hydrazine vapors by feeding them directly into an incinerator. There is concern about vapor detonations when attempting to destroy hydrazine vapors without prior absorption in water. Vapor detonations can propagate from the hot reactor through very narrow tubing into the reservoir of the hydrazine vapors that are to be destroyed, but this can be done only slowly in high dilution and in a controlled manner.

There may be concern over the flashback of flames into gas streams undergoing treatment if hydrazine concentrations exceed safe limits, but some intrepid investigators nevertheless recommend the use of hydrazine decomposition catalysts to remove hydrazine vapors from gas streams vented during depressurization of rocket propellant tanks. Another concern would be that during an inadvertent reversal of gas flow toward the end of depressurization (e.g., caused by brief non-destructive deflagration puffs), catalyst fines could be blown back into the propellant tank. One such patented catalyst contains mainly manganese(IV) dioxide plus mixed oxides of lanthanide rare earth metals [1548]. Another proposed catalyst contains rare earth/transition metal oxide mixtures and is said to be capable of treating hydrazine concentrations of 4000 to 5000 mg/L at space velocities of  $10000\text{ h}^{-1}$  at 287 K [1547]. The claimed concentrations are most likely an error that occurred in translation, because this would be a flammable and explosive vapor mixture. Even at  $5000\text{ }\mu\text{g/L}$  in air and even in nitrogen instead of air, this is a potentially hazardous operation. Flashback is most likely to occur toward the end of the blowdown operation when the flow rate drops to near zero. It would be necessary to dilute the vented gas with inert gas to below detonable concentrations (partial pressures below  $1.07\text{ kPa} = 8\text{ mm Hg}$ ).

At NASA KSC, the handling of propellants is confined to a few select areas operated by well-trained personnel. In contrast, H-70 powered EPU in F-16 fighter maintenance is done at many air bases around the world. Pressurant gas from spent F-16 EPUs containing H-70 blend is usually vented through a 7.5-L (2-gal) stainless-steel bucket containing 3.8 L (1 gal) of ordinary chlorine bleach (5% NaOCl). As an alternative, a transparent cartridge containing a dry chemical (100 g alumina granules impregnated with potassium permanganate  $\text{KMnO}_4$ ) has been tested [2021]. The  $\text{KMnO}_4$  undergoes a highly visible color change from purple to brown as a result of hydrazine absorption. Venting of a single F-16 EPU discolors approximately half the contents. Sixty percent of the hydrazine in the vent gases is destroyed by reaction with the dry chemical, while 40% remain adsorbed on the exhausted portion of the dry chemical. The cartridge would require secondary treatment before it may be disposed of safely. One of the cleanest methods for hydrazine disposal is the reaction with oxygen or ozone, as was discussed earlier in Section 3.1.1.1 (“Oxidation of Hydrazine”).

### 7.11.2 Cryogenic Cold Trap Scrubbers

A LN<sub>2</sub>-cooled cryogenic cold trap has been evaluated for the removal of MMH vapor from vented pressurant gases; presumably the same method would work for trapping hydrazine vapors from vented pressurant gases [2022].

## 7.12 Hydrazine Wastewater Decontamination

### 7.12.1 Neutralization and Disposal of Diluted Rinse Waters and Scrubber Solutions

There are many situations during the use of hydrazine(s) in the aerospace and electric power industries where dilute hydrazine-containing rinse waters must be disposed of:

1. Rinse waters accumulate after system-level tests (expulsion tests, vibration tests, spin tests, acoustical tests) with hydrazine tanks in missiles and satellites.
2. Transfer hoses must be rinsed before storage and reuse.
3. Hydrazine and MMH or UDMH rail and road tank cars must be hydrotested once every year and are rinsed clear of propellant prior to the test with water (periodic pressure tests are required by DOT).
4. Unreacted hypergolic propellants dissolve in cooling water on flame deflector chutes during ground testing or launch of NTO/UDMH or NTO/Ae-50 engines, where they form NDMA.
5. Condensate and blowdown from steam power plants where hydrazine hydrate was added for boiler feedwater deoxygenation.

Wastewater at rocket test sites would result from rinsing containers that contained hydrazine and from rinsing hardware that has gone through development, qualification, or quality control acceptance test firings. Wastewater also is produced by vapor scrubbers, although that water also contains scrubber chemicals like citric acid or ketoglutaric acid.

Launch operations at NASA KSC and CCAFB generate large volumes of hydrazine-laden wastewater for disposal. Some of this waste is contained and shipped out for subsequent disposal by incineration, which makes it a very expensive operation. Alternative remediation methods evaluated by NASA and contractors include oxidative and reductive pathways as well as biodegradation in fixed film reactors.

Hydrazine and hydrazine-type fuels that are contained in wastewater constitute a more diffuse source of contamination than undiluted propellants. This problem arises with wastewaters discharged from fuel-blending facilities [2023], rocket test/launch sites, and fossil-fired or nuclear steam power plants. Comparison of the various hydrazines and their resistance to autoxidation (Section 3.1.1.1) reveals that the alkylhydrazines are generally more difficult to dispose of than hydrazine itself. Occasionally, hydrazine-containing boiler feedwater must be discharged if the boiler is shut down for repair. Depending on the location of the power plant, it may not be permissible to dump this water without pre-treatment and removal of the

**Table 76:** Wastewater generation as a result of propellant handling operations.

| Propellant           | Propellant, L | Wastewater, L              |
|----------------------|---------------|----------------------------|
| <b>Fuel</b>          |               |                            |
| MMH                  | 58000         | All three combined: 718000 |
| Aerozine-50          | 77000         |                            |
| Hydrazine            | 14300         |                            |
| <b>Oxidizer</b>      |               |                            |
| Dinitrogen tetroxide | 164000        | 132000                     |
| Total                | 313300        | 850000                     |

Data source: [2024]

hydrazine. Power plant effluents also contain organic amines like cyclohexylamine or morpholine for pH adjustment in addition to hydrazine.

It is of interest to compare the volume of wastewater generated in relation to the amount of rocket propellants handled for a typical rocket launch site such as NASA KSC for a typical year, based on data collected in 1985. As shown in Table 76, the amount of wastewater generated is a multiple of the volume of rocket fuels used.

The safe and environmentally acceptable disposal of all that wastewater is indeed a difficult task. The amount of oxidizer waste is less and is shown here only for comparison. What is not shown behind these numbers is that the waste treatment requirements and government environmental regulations have created a shadow army of inspectors and waste processors that significantly contributes to the overall expense of getting payloads into orbit. It would be interesting to plot the growth of environmental and safety jobs at launch sites as a function of time since the creation of EPA and OSHA.

**7.12.1.1 Neutralization of Hydrazine Rinse Solutions**

In some cases, it is beneficial to neutralize (adjust the pH and thus minimize evaporation) hydrazine solutions before they are subjected to destructive disposal. It has been suggested to use dilute solutions of glycolic acid (hydroxyacetic acid) as rinse water for cleaning of hydrazine components, e.g., Ae-50 flow meters after calibration with actual propellants [2025]. Glycolic acid is only a weak acid and not likely to cause damage to the hardware being cleaned, as long as all residual acid is flushed out with water. Wetting agents and antifoaming agents may be added to the cleaning solution as necessary. The odor of glycolic acid is not as objectionable as that of acetic acid, which could be used for the same purpose. Glycolic acid is biodegradable.

**7.12.1.2 Hydrazine Wastewater Decontamination by Autoxidation by Aeration with Air**

Although most of the methods described here were developed for the removal of hydrazine hydrate from power plant wastewater, they can be just as well applied to the

removal of hydrazine from other wastewater streams, such as those that may originate in hydrazine manufacturing plants, rocket test stands, or rinse waters from freshly reduced polymers. The easiest way to remove hydrazine from wastewater is to aerate the water in the presence of activated charcoal that acts as a catalyst [2026–2028]. The number of periodical publications is dwarfed by the number of patents issued for this procedure. The tightening requirements for the removal of hydrazine from blowdown in power plants before releasing the contaminated blowdown and condensate into surface waters has brought about a decade-long flurry of patenting activity, mostly in Japan, of different methods for removal of hydrazine from dilute aqueous solutions. The most widely practiced method is the aeration of hydrazine solutions over packed beds or in a trickle bed of activated charcoal [2029–2031]. However, activated charcoal may become inactive with extended use. In this case, it can be regenerated by treatment with 1% hydrogen peroxide solution and then returned to active hydrazine service [2032]. Thus, aerating 0.05 to 0.5% activated charcoal powder or granules slurried in 100 to 1000 ppm  $\text{N}_2\text{H}_4$  in  $\text{H}_2\text{O}$  will rapidly reduce the concentration to less than 1 ppm [2033]. Adding 100–1000 ppm  $\text{Fe}^{3+}$  to the solution at a  $\text{pH} > 8$  ( $\text{pH} 10$  preferred) will speed up the process. This is a batch process where the treated material must sit in a settling pond for a while to allow the charcoal and hydroxide sludge to settle. The sludge can be reused. The destruction of hydrazine can be completed by sodium hypochlorite. An eventual excess of active chlorine can be removed by passing the solution once more over activated charcoal. In one design example using activated charcoal in a six-stage fluidized system with 1 h retention time, bubbling  $23 \text{ m}^3/\text{h}$  air, containing 48 kg charcoal per stage, the hydrazine concentration at the entrance to the system and successive exits from the six stages was 400, 260, 165, 95, 50, 15, and, finally, 0 ppm [2034]. Aeration in the presence of copper turnings or copper salts reduced the hydrazine content of wastewater from 163 to 3 ppm after only 1 h [2035, 2036]. A similar patent proposes aeration with copper turnings first, followed by cation exchange [2035]. Aeration with the addition of copper(II) sulfate, copper(II) chloride, or copper(II)oxide as catalysts will quickly remove unwanted hydrazine [2037]. A USSS No. 10 to 24 size Raney copper catalyst containing 9.6% Al was packed into an aerated column and used for treating a hydrazine solution containing 250 ppm [2038], thereby reducing the hydrazine concentration to 0.02 ppm. Aeration in the presence of a manganese(IV) dioxide granular catalyst removed most of the hydrazine, and remaining traces of hydrazine could be removed with sodium hypochlorite or hypochlorous acid  $\text{HOCl}$  [2039]. The manganese(IV) dioxide catalyst can be coated on a fabric of synthetic polymer fibers through which the solution flows [2040]. Aeration in the presence of a granular nickel peroxide catalyst is equally effective [2041]. Another variant of this process treats the waste solution in the presence of a nickel oxide or nickel peroxide slurry and adds hydrogen peroxide or sodium hypochlorite to the stirred slurry to regenerate the catalyst [2042, 2043]. Yet another variant of this process mixes the hydrazine with hydrogen peroxide first, then passes the mixed solutions over a bed of nickel peroxide pellets [2044].

The nickel peroxide pellets can be formed and extruded with the aid of a cement binder [2045]. It is known that iridium is a good catalyst for the decomposition of anhydrous hydrazine in rocket engines, but it may be prohibitively expensive to use iridium (<20% Ir) on activated charcoal as catalysts for autoxidation of hydrazine wastewater solutions [2046, 2047].

Palladium is not as expensive as iridium and may serve the same purpose equally well. Palladium catalysts catalyze the autoxidation of hydrazine solutions in air, also in combination of air with hydrogen peroxide [2048–2050]. Concentrations of 200 ppm  $\text{N}_2\text{H}_4$  and more in wastewater can be removed by the addition of hydrogen peroxide and additional aeration in the presence of a palladium catalyst [2051]. Residual hydrazine concentrations after 3.5 h were less than 1 ppm.

Palladium-coated wire mesh catalysts used for hydrazine removal, as well as from effluents of ketazine hydrazine production plants, can be regenerated by treatment with sodium hydroxide at  $\text{pH} > 13$  or 0.1% hydrogen peroxide solutions [2052–2055]. Palladium catalysts with aeration allow the removal and destruction of hydrazine at  $\text{pH}$  8.6–11 from the regeneration effluent of ion-exchange resins used for the demineralization of recycled boiler condensate [2056]. Using oxygen-enriched air diminished the necessary contact time to  $1/2$  to  $1/3$  of that required with normal air [2057].

Catalysts proposed for the removal and autoxidation of excess hydrazine in the condensate that leaves steam power plants as wastewater include cobalt(III) complexes such as sodium hexanitritocobaltate(III) or cobalt(III) hexammino chloride [2058]. Wastewater containing small hydrazine concentration can be purified more rapidly by aerating it in the presence of UV light [2059].

### 7.12.1.3 Hydrazine Wastewater Decontamination by Ozone Treatment

Ozonization (synonym: ozonation, ozonolysis) in combination with UV illumination has been used in drinking water sterilization with good success. Commercial ozonation units are available from several vendors to destroy dissolved organic contaminants present in groundwater and wastewater with low levels of suspended solids [2060]. The system uses a combination of UV radiation, ozone, and hydrogen peroxide to effectively oxidize most contaminants.

One of the most complex tasks in the disposal of hydrazine-contaminated rinse waters was faced by the cleanup contractors for the Hydrazine Blending and Storage Facility at Rocky Mountain Arsenal near Denver, CO in the 1980s. Several cleanup contractors surveyed the site, continued to take air, soil, and groundwater samples and proposed remedial action for the 300000 gal of contaminated rinse water still stored at the site. Since in 1982 there was no demonstrated proven technology for the total decontamination of UDMH/NDMA-contaminated rinse water, a survey of available and proposed wastewater decontamination technologies was started. Several techniques were evaluated in bench- and pilot-scale setups, including UV/ozonation and UV/hydrogen peroxide treatment [2061], or adsorption on activated charcoal [2062]. As one of several interim response actions being conducted at Rocky Mountain Ar-

senal under Superfund legislation, UV/chemical oxidation was chosen as the best process for the treatment of approximately  $1130\text{ m}^3$  (300000 gal) of hydrazine- and NDMA-contaminated rinse water [2063]. Because the project action level for NDMA was 1.4 pg/L (1.4 ppt) and because the hydrazine fuels decompose before NDMA is destroyed to the action level, 1.4 pg/L of NDMA was targeted as the goal for treated effluent. The UV/chemical oxidation process typically can treat hydrazine compounds in 16 h, while 35 h are required to decrease the NDMA concentration to approximately 1 to 2 ppb ( $\mu\text{g/L}$ ), which still does not meet the treatment goal of 1.4 pg/L. Investigating a possible secondary treatment that could reduce NDMA concentrations even further, Rocky Mountain Arsenal and the US Army Engineer Waterways Experiment Station attempted to achieve a lower effluent level without costly additional UV/chemical oxidation treatment. Three adsorption processes, granular activated carbon (GAC), organic-based ion-exchange resins, and activated alumina, were evaluated, but the results were not satisfactory [2062]. Three different vendors offered equipment for this task, including ozone/UV and hydrogen peroxide/UV treatment. These were first tested in pilot-scale operations at the 3780 L/batch level. All techniques had the potential for generating NDMA from UDMH as an undesirable intermediate of the disposal process. Thus, if the hydrazine wastewater disposal process had to be interrupted for an unforeseen reason, one would be stuck with an even larger quantity of NDMA-containing wastes. The capacity of the system was selected such that two parallel systems could treat  $1130\text{ m}^3$  (300000 gal) of wastewater over a 7-month period or 18900 L/week/system (5000 gal/week/system). The target post-treatment tolerable concentration of NDMA was established as 1.4 ppt (parts per trillion), or the lowest achievable certified reporting limit. NDMA concentration in the untreated wastes stored on site ranged from 2.9 to  $360\text{ }\mu\text{g/L}$ . In addition to new treatment techniques, analytical methods for analysis of NDMA in wastewater in the presence of unreacted hydrazines had to be developed and certified to meet government requirements.

In addition to treating waste that had been stored above ground in tanks, groundwater collected at various intercept points to prevent it from flowing off-site had to be treated [2064]. Two activated granular charcoal systems were not effective in removing NDMA from groundwater. Analysis of inflow and effluent streams indicated that NDMA may merely be recirculated through the system without appreciative removal. NDMA concentrations between 0.04 and  $5\text{ }\mu\text{g/L}$  have been recorded at these locations. Use of an ozone/UV technique would require treatment times in excess of 50 h to achieve the desired removal to the non-detectable level. In addition, alternative adsorption methods were evaluated.

Ozone instead of air as a decontaminating agent (without enhancement by UV radiation) is useful for unsubstituted hydrazine only [2065]. Ozonation products of wastewater containing hydrazine and hydrazine-related rocket fuels were characterized [575, 2066]. Minor amounts of nitrate were produced from the ozonation of hydrazine, MMH, and UDMH. This was probably a result of ammonia or nitrosamine oxidation.

The rates of oxidative destruction of hydrazine, MMH, and UDMH were investigated using ozone alone or ozone activated with UV [2067]. All three hydrazines were oxidized rapidly with ozone or ozone/UV. The ozone was consumed as rapidly as it was introduced as long as any hydrazine was present. The limited solubility of ozone in water is one of the rate-limiting factors. Metal catalysts accelerated the destruction of hydrazines and NDMA [2068, 2069]. Operation at pH 9.1 for destruction of hydrazines was recommended for optimum results. The rate at which the three hydrazine fuels were destroyed was about six times slower at pH 2.5 than at 9.5. Three different methods for treatment of hydrazine wastewaters were tested at IITRI: ozone as the primary oxidizing agent, UV light as a catalyst for the reaction between NDMA and ozone, and, finally, chlorine as a final “polishing” agent following the treatment with either of the two aforementioned methods [2070]. Three different reactors were used in the study: a tubular reactor containing a liquid column and a gas dispersion (sparging) element at the bottom, a UV spray chamber with two different quartz lamps (high-pressure and low-pressure mercury lamps), and a commercial UV water purifier consisting of a CRES-316 tube with a coaxial quartz tube holding the UV lamp. Chlorination was not pursued any further because halocarbons are not permitted in the effluent of the treatment plant. The combination of ozone and UV was able to reduce the NDMA concentrations to below 20 ppt.

Modeling of the kinetics of hydrazine ozonolysis showed that fuel destruction rates were limited by the rate of ozone input [573]. Using a stopped-flow technique, it was shown that while the overall, global destruction was rapid, observed “rate constants” were five to six orders of magnitude lower than the true kinetic rate constants ( $10^7$  to  $10^9$  L mol<sup>-1</sup> min<sup>-1</sup>). Initial mol ratios of fuel to ozone consumption were about two to five, and this ratio decreased to less than unity or even less than unity as the ozonolysis proceeded. The same UV-ozonolysis installation that was originally developed for hydrazine wastes can also be used for the destruction of other industrial organic wastes generated during routine operations [2071, 2072].

NASA WSTF acquired an ozone generator capable of producing 2.75% ozone in oxygen and installed it in a pilot-scale reactor [2073–2075]. It was important to feed the ozone generator with dry oxygen and maintain its temperature below 287 K to optimize the ozone yield. The UV ozonator reactor was a rectangular chamber with six spray nozzles capable of flowing 3.8 L/min and atomizing the liquid into a fine spray. The residence time of the droplets during each passage was ~14 s. Twenty-three low-pressure UV lamps rated at an average output of 6.6 W of UV light were mounted through the sides of the chamber. The power consumption of the UV lamps was 152 W. Experiments with hydrazine lasted 78 h, MMH 180 h, and UDMH 334 h. Ozone dissolves in cold water better than in hot water.

NASA WSTF then fabricated and tested a full-scale 85.2-m<sup>3</sup> (2250-gal) hydrazine wastewater treatment system [2076]. The system was based on an IITRI design featuring the use of ozone and UV to destroy the hydrazines and NDMA. A series of 21

tests evaluated the performance of the system using synthetic mixtures of hydrazine, MMH, and UDMH at 100- and 3900-ppm concentration levels. In addition, one of these tests was performed on actual wastewater obtained from a Vandenberg Air Force Base launch site sump. The tests demonstrated that the UV ozonation system would satisfactorily reduce the hydrazine concentration to less than 5 ppb and the NDMA concentration to less than 100 ppt. Hydrazine-containing wastewater can be decontaminated by treatment with ozone at pH > 7.0 and in the presence of bromide [2077, 2078].

NASA conducted a pilot-scale study to evaluate the efficiency of UV radiation and ozonation technology of an Ultrox UV ozonation system for the on-site destruction of propellant (hydrazine) wastewater generated at NASA KSC [2079]. The Ultrox Model P-75 was a skid-mounted unit containing separate modules that were integrated as a single unit, including a UV radiation and oxidation reactor module, an ozone generator module, a hydrogen peroxide feed system, and a catalytic ozone decomposer. The study demonstrated the capability to effectively destroy all three hydrazine propellants tested, their associated impurities, and toxic oxidation products such as NDMA. The Ultrox system achieved removal efficiencies exceeding 99% for different waste types and waste matrices such as hypergolic fuel in citric acid solution, hypergolic fuel in a combined wastewater, and organic solvents in an oil/grease wastewater. Hydrogen peroxide has been observed as an intermediate in the reaction of ozone with solutions of hydrazinium salts [574].

#### 7.12.1.4 Hydrazine Wastewater Decontamination by Chlorine, Hypochlorite, and UV Chlorinolysis

In solutions that contain only hydrazine and no alkylhydrazines, oxidation by hypochlorite is the standard and most effective method of hydrazine destruction [2080, 2081]. Hypochlorites are most economically available as sodium hypochlorite solution (chlorine bleach, often used as a disinfectant and laundry additive) and as calcium hypochlorite, a solid (commercially available as HTH<sup>®</sup>), often used as a swimming pool disinfectant. Commercial sodium hypochlorite solution typically contains 5.2 mass-% NaOCl, corresponding to 2.5% active chlorine. Commercial HTH<sup>®</sup> typically contains 68% active chlorine in the form of its active ingredient calcium hypochlorite Ca(OCl)<sub>2</sub>. The hydrazine neutralization reactions proceed according to

The reactions are exothermic, and the large amount of nitrogen gas evolving may carry unreacted ingredients as an aerosol out of the system. Assuming an NaOCl content of 5.24 mass-% in the commercial sodium hypochlorite solution, 59 kg of bleach would be required for each kg of HH100 (100% hydrazine hydrate = 64 mass-% N<sub>2</sub>H<sub>4</sub> in water). The hydrazine solutions should be diluted to below 35% N<sub>2</sub>H<sub>4</sub> before attempting

to neutralize them. Sodium hypochlorite solutions decompose during storage and lose active chlorine due to disproportionation to chloride and chlorate. Better storage stability and higher storage density can be achieved with calcium hypochlorite. It can be stored as a dry powder and must be dissolved in water to form solutions containing no more than 10 mass-% HTH before attempting to neutralize hydrazine solutions containing no more than 35%  $\text{N}_2\text{H}_4$ . 45 kg of a solution containing 4.5 kg HTH is required for the disposal of 1 kg of HH100.

The following section initially deals with the disposal of all three propellant hydrazines, but there are specific sections for MMH and UDMH disposal contained in the chapters “Methylhydrazine” and “Dimethylhydrazines.” Chlorinolysis of hydrazine at pH 4 was found to be an effective method for the destruction of hydrazine in the absence of MMH or UDMH without the formation of detectable annoying byproducts [2082, 2083].

The chemistry and kinetics of chlorinolysis activated by UV light as a means of disposal and neutralization of dilute aqueous hydrazine, MMH, and/or UDMH solutions were investigated in the laboratory and with a 113-L (30-gal) pilot reactor. On the basis of these results, a process to treat a minimum of  $7.5\text{ m}^3$  (2000 gal) of contaminated wastewater per day was developed [2084].

One of the studies [2003] illustrated the hazards of trying to decontaminate hydrazine spills with dry calcium hypochlorite (HTH) powder: The mixture ignited instantaneously. Even household bleach can cause pooled undiluted H-70 fuel to ignite. The worst instructions for the disposal of hydrazine were found in a government manual and are quoted here as an example of poorly written safety instructions: “*Hydrazine can be neutralized by mixing 7–10 pounds of calcium hypochlorite (HTH) with one pound of hydrazine.*” This is most certainly asking for trouble and is quoted here only as an example of how **not** to do it. Again, for safe operation, hydrazine should be diluted with water to less than 35%  $\text{N}_2\text{H}_4$  first, and the HTH powder needs to be dissolved in water first and then added as an aqueous solution with a maximum of 6% active chlorine.

Using more advanced GC/MS and GC/FTIR instrumentation, later investigators [2085–2087] found a mixture of 90 to 100 compounds resulting from the reaction of UDMH with sodium hypochlorite, not all of which could be identified. Aniline, which was known to be present in propellant-grade hydrazine in concentrations up to 0.5%, became oxidized only after all hydrazine was consumed and the gas evolution had ceased. As a result of its aniline content, the solution turned pale yellow immediately after all hydrazine was consumed. No unreacted aniline was found, but the colored reaction products were not yet identified. The concern about aniline as a contaminant in anhydrous hydrazine is now a thing of the past because it is no longer used.

#### 7.12.1.5 Hydrazine Wastewater Decontamination by Hydrogen Peroxide

Hydrogen peroxide is used for the decontamination of many industrial wastewater streams, in particular in pulp mills. Ideally, the reaction of hydrogen peroxide with

hydrazine would lead to only nitrogen and water, innocuous reaction products that can be released to the environment:

However, under certain pH conditions, the reaction can also lead to hydrogen azide, which is toxic and explosive. The presence of traces of copper ion is essential to avoid azide formation and achieve oxidation to water and nitrogen.

For the decontamination of wastewater from rocket test and launch sites, of course, it is always cheaper to use air instead of hydrogen peroxide as an oxidant. However, in special situations it may be advantageous to use hydrogen peroxide as an oxidant instead because the reaction is faster and goes to completion within the confines of the apparatus. In either case, air or hydrogen peroxide oxidant, the destruction of hydrazine is accelerated if the solution is passed through a tower packed with activated charcoal catalyst [2088] or if the reaction is carried out in the presence of copper salts [2089].

A mixture of hydrogen peroxide with iron(II) salt solutions is a strong oxidizing agent (Fenton reagent) with free hydroxyl radicals. This oxidant is capable to convert many organic contaminants to carbon dioxide. The complete conversion of organics to  $\text{CO}_2$  is also called mineralization.

A mobile apparatus was described that destroys hydrazine with hydrogen peroxide with a Pd-coated anion exchanger as catalyst [2090]. Low hydrazine hydrate concentrations in the blowdown condensate water from power plants can be neutralized with hydrogen peroxide in the presence of Cu(II) ions as catalysts, enhanced by bubbling air through the solution [588, 2091]. The oxidation of hydrazine in aqueous solutions at substantial rates takes place only in an alkaline medium and in the presence of catalysts, such as the ions of transition metals. The catalytic activity of the metal ions in the solution increases in the sequence  $\text{Fe} < \text{Co} \ll \text{Cu}$ . Hydrazine in the cooling water of primary and secondary water loops of nuclear power plants would decompose by radiolysis while near the core of the reactor, and the decomposition by radiolysis was compared to the destruction by hydrogen peroxide, the technique used for decontamination of hydrazine hydrate containing condensates in steam power plants before the water can be released to surface waters [592, 2092]. The rate of hydrazine disappearance during hydrogen peroxide treatment was measured as a function of copper ion concentration, pH, and temperature. Hydrazine destruction by reaction with hydrogen peroxide with a trace of copper ion was very slow at  $\text{pH} < 3$  but complete at  $\text{pH} = 5$ .

Neutralization and detoxification of wastewater from the production of hydrazine hydrate is more difficult due to the high salinity of the wastewater from Raschig processes and the presence of organics from the ketazine and PCUK processes [2093]. Hydrazine-containing wastewater can be treated with hydrogen peroxide in the presence of freshly precipitated, finely divided, suspended copper hydroxide as a catalyst [2094].

#### 7.12.1.6 Hydrazine Wastewater Decontamination by Bioremediation

The disposal of wastewater containing hypergolic propellants (including MMH rinse waters) by keeping them in an open holding pond with bioregeneration through water hyacinths has been tested in Florida [1891, 2095]. Similar methods will work for wastewater containing just hydrazine and no MMH. Active contributions by sunlight-induced oxidation reactions may accelerate the biological digestion process.

Although the use of biological mechanisms has been successfully applied to the cleanup of numerous chemical contaminants, the concentrations of hydrazine at a spill would prove toxic to conventional microbes. It was concluded that research conducted in the period 1975–1995 has had little success in providing a hydrazine-tolerant microbe [2096]. This 1996 conclusion contradicts other findings that some soil bacteria thrive on dilute hydrazine and can digest it [2097, 2098]. It appears that those investigators were mostly looking for immediate, swift treatment methods for undiluted H-70 spills [2096], but failed to include downstream bioremediation of more dilute spills and rinse waters or hydrazine rinse water that had already soaked into soil.

Hydrazine concentration levels typically associated with hydrazine wastewater from rocket test sites would require a dilution of at least 100 to 1 for effective biological degradation. At low concentrations of hydrazine, the presence of bacteria doubled the rate of hydrazine oxidation. This increase of oxidation was attributed to cellular metabolism. The results of the toxicity studies showed that hydrazine was least toxic to *Nitrosomonas*. Because *Nitrosomonas* had the ability to survive at doses toxic to other bacteria, it was chosen for further study. Because hydrazine seriously affects the natural bacterial balance in the aquatic environment, the researchers [2099] concluded that hydrazine contamination in a natural aquatic environment can be expected to seriously disrupt bacterial populations.

Wastewater with any or all of the three propellant hydrazines can be decontaminated in a holding pond stocked with aquatic plants (common water hyacinth, *Eichhornia crassipes*, water cabbage *Pistia stratiotes*) [2100].

#### 7.12.1.7 Hydrazine Wastewater Decontamination in Active Sludge Processes

Active sludge processes are conducted in closed digesters for the treatment of municipal sewage. Pulsed and continuous loads of hydrazine at concentrations up to 10 g/L did not affect the methane-forming capability of an active sludge sewage treatment process, and the hydronitrogen was digested as a welcome nutrient for bacteria growth [2101]. Apparently, some of the sewage treatment plant bacteria are not only tolerant of hydrazines (up to certain limits) but will also digest them and thrive on them. At concentrations of <5 mg  $\text{N}_2\text{H}_4/\text{L}$ , wastewater can be treated directly in aeration tanks. At >5 mg  $\text{N}_2\text{H}_4/\text{L}$ , the waste is treated with excess activated sludge in pre-aeration tanks, followed by aeration treatment [2102]. Complete removal can be achieved at process parameters typical for conventional biochemical treatment plants. Based on this information, hy-

drazine in small concentrations could possibly be mixed in with fecal wastes and the treatment plant would not even notice its presence.

Hydrazine in wastewater can be degraded by effective microorganisms added to sewage that contains hydrazine. The changes in hydrazine concentration under different conditions, such as microorganism content, pH, temperature, and hydrazine concentration, were analyzed [2103]. Under the conditions with a temperature of 303 K (30 °C), pH of 8.0, and a microorganism content of 5%, the microorganisms proliferated in the complex culture medium within 3.5 d and had a high hydrazine degradation rate. It was demonstrated that under the laboratory conditions, hydrazine can be degraded effectively by microorganisms.

#### **7.12.1.8 Hydrazine Wastewater Decontamination by Electrolytic Oxidation**

The environmentally most friendly method of removing excess hydrazine from dilute aqueous solutions (in the absence of other reductants) is electrolytic oxidation, which does not introduce any additional chemicals and does not increase the salinity of the wastewater [2104]. The electrodes used for the removal of hydrazine from water and other electrolytes can also be purged and depolarized with air as in a fuel cell [2105–2107].

Hydrazine and/or UDMH in wastewater in the concentration range 100 to 800 ppm can be destroyed by direct electrolysis with a stainless-steel cathode and a carbon, lead, or nickel anode [2108]. Disodium hydrogen phosphate was added to increase conductivity and pH was adjusted with phosphoric acid.

Electrolytic oxidation has also been evaluated for the removal of UDMH [2109]. Another technique considered is electrodeionization [2110]. These methods will also work for the removal of hydrazine.

Instead of using electrical energy for electrooxidation of hydrazine in wastewater, deoxygenated hydrazine wastewater streams with the correct hydrazine concentration can be fed to a fuel cell with air used for depolarization of the opposing cathode, thereby generating electrical power instead of consuming it for waste detoxification [2111]. The cell includes a solid polymer electrolyte sandwiched between electrodes that have three-dimensionally complex, high-surface-area structures and contain appropriate electrocatalysts. The solid polymer electrolyte separates the anodic compartment from the cathodic compartment. Thus, there is no mixing of rinse-water-containing hydrazine with any oxidant, and therefore the undesirable formation of nitrogen oxides, nitrite, or nitrate is prevented. The system can easily be automated, requires little maintenance, and can be operated without much training. The cell can be operated in an electrolyzer or fuel-cell mode: if the concentration of hydrazine is sufficiently high, the cell can be operated as a fuel cell; otherwise, the cell can be operated as an electrolyzer. If the concentration of hydrazine is enough to enable operation in the fuel-cell mode, then the power generated by the system could offset some or all of the cost of treatment.

#### 7.12.1.9 Hydrazine Wastewater Decontamination by Photocatalytic Oxidation

A variety of  $\text{TiO}_2$  suspensions,  $\text{TiO}_2$ -coated glass films, and  $\text{TiO}_2$ -coated foils have been used to destroy UDMH in water by photocatalytic oxidation (chapter “Dimethylhydrazines,” Section 1.6.6.16) and the same methods should be usable for the destruction of hydrazine, generally a simpler chemical reaction. Photocatalytic degradation of hydrazine in aqueous solution was studied under ambient conditions using UV radiation and nano-sized anatase titania ( $\alpha\text{-TiO}_2$ ) synthesized by an anhydrous sol-gel route [2112]. Degradation of hydrazine was followed by a complexometric spectrophotometric procedure to derive the kinetics of degradation.

#### 7.12.1.10 Hydrazine Wastewater Decontamination by Reversible Adsorption

Hydrazine can be reversibly adsorbed from dilute aqueous solutions onto zeolite [2113]. After the zeolite is saturated, it is air dried at 383 K, then heated to 673 K to burn off the hydrazine; it can be recycled for the same use repeatedly. Sorbents made from aluminum triphosphates  $\text{H}_2\text{AlP}_3\text{O}_{10} \cdot 2\text{H}_2\text{O}$  or chromium(III) triphosphates  $\text{H}_2\text{CrP}_3\text{O}_{10} \cdot 2\text{H}_2\text{O}$  were patented for the removal of the last traces of hydrazine from waste streams [2114].

#### 7.12.1.11 Hydrazine Wastewater Decontamination by Irreversible Absorption

Hydrazine and alkylhydrazines may be absorbed onto crosslinked polyvinylpyrrolidone that is added to the contaminated water in the form of a latex suspension. The hydrazine-loaded latex will precipitate and can be filtered off [2115].

#### 7.12.1.12 Hydrazine Wastewater Decontamination by Sonolysis

Intense ultrasound in a resonating cavity in water will cause cavitating bubbles that allow accelerated interaction with dissolved air or added hydrogen peroxide. The degradation of 0.1 and 1.0 mmol/L hydrazine in water was investigated as a function of pH under stirring and ultrasonic irradiation (200 kHz, 200 W) conditions [2116, 2117]. It was found that the hydrazine degradation depended greatly upon pH under ultrasonic irradiation condition, while it did not take place over the whole pH range (0.8–9) under the stirring condition. The hydrazine degradation may be achieved by OH radicals. A suspension of coal ash aids the degradation of hydrazine but inhibits the formation of OH radicals [2118, 2119].

#### 7.12.1.13 Hydrazine Wastewater Treatment by Reaction with $\alpha$ -Ketoglutaric Acid

$\alpha$ -Ketoglutaric acid (= 2-ketoglutaric acid, AKGA,  $\text{HOOCCH}_2\text{CH}_2\text{C(O)COOH}$ ), a water-soluble solid, has been proposed for hydrazine or MMH vapor absorption from air (Section 7.11.1) or for the decontamination of wastewater from rinsing hydrazine- or MMH-contaminated rocket propulsion systems [2014, 2015, 2120]. Hydrazine and MMH wastewater neutralization by reaction with alpha-ketoglutaric acid (AKGA) to form the stabilized pyridazine derivatives PCA and mPCA has been explored. Similar

reactions with alpha-ketoglutaric acid for the removal of hydrazine vapors from vented pressurization gases were already discussed earlier in Section 7.11.1.

Questions remain concerning the completeness of the reaction, 100% scavenging of hydrazines to be removed, and potential hydrolysis of pyridazines in wastewater ponds, releasing the hydrazines again. Pyridazines are not very soluble in water and are likely to clog process equipment.

A critical review of the patent claims and preliminary laboratory tests with  $\alpha$ -ketoglutaric acid for the decontamination of vapor scrubber effluents or rinse water from hydrazine- or MMH-contaminated rocket propulsion systems concluded that the uncertainties of the completeness of the reaction and lack of complete identification of all reaction products prevented the practical application of this chemical under real-life rocket launch site GSE conditions [2018]. When reacting 0.73-M AKGA solutions in benchtop lab tests, a solid formed with hydrazine but not with MMH. In more dilute 0.2-M AKGA solutions, no precipitate formed with either hydrazine or MMH. Another keto compound tested in hydrazine or MMH scrubber liquids was ethyl acetoacetate  $\text{H}_3\text{C}-\text{C}(\text{O})-\text{CH}_2-\text{C}(\text{O})-\text{O}-\text{CH}_2\text{CH}_3$ , but its reaction with hydrazine or MMH produced a gummy, sticky substance (a carbinolamine intermediate converting to 3-methylpyrazol-5-one) that clung to the walls and was difficult to remove.

### 7.12.2 Disposal of Hydrazine Production Process Wastes

Some of the methods used for the removal of hydrazine from hydrazine production waste streams can also be used for the decontamination of wastewater streams from rocket test and launch sites. Hydrazine and acetone contained in the saline wastewater effluent from production plants using the Bayer ketazine process can be cleaned by bacterial treatment using salt-resistant bacteria scooped from the Great Salt Lake [2121]. After stripping the volatile ketazine, residual hydrazine in Bayer-process plant effluents can be removed by chlorination [2122–2124].

### 7.13 Off-Loading of Hydrazine from Spacecraft

Occasionally it becomes necessary to off-load (de-tank) propellants from a fueled satellite or space probe because the launch date has been postponed or because

repair work on a damaged spacecraft cannot be conducted in proximity to loaded propellants.

In the past, propellant off-loading has become necessary for GALILEO (MMH and NTO), ARTEMIS (MMH), ROSETTA (MMH) [2125], and MEASAT-B (anhydrous hydrazine and NTO) [2126]. All spacecraft in this category used bipropellant systems and tanks with surface tension PMDs. In most cases only the fuel was removed, and the oxidizer was left in the tanks, because its removal or depressurization might introduce gas bubbles into the capillary gallery or the bubble traps and cause loss of NO from MON. Also, the evaporation of NTO or MON leaves behind a thin film of nitric acid, which would make the corrosion environment even worse than in NTO. There are no generally accepted guidelines for off-loading of propellants from spacecraft, so the personnel in charge of the operations had to develop their own procedures. Some spacecraft do not even have a drain at the lowest point in the system to allow all liquid to be drained by gravity. Other line-plumbing systems may have check valves that allow liquid to flow in only one direction, into the tank, and not out of the tank. Most plumbing schematics have dead-ended passages where propellants will pool and cannot be removed by flushing.

#### **7.14 Inerting of Decommissioned Satellites and Upper Stages in Orbit**

The fragmentation of a PEGASUS HAPS upper stage on June 3, 1996, stands as one of the worst accidental satellite breakups on record in terms of cataloged orbital debris scattered. Orbital debris constitutes a hazard for other satellites in similar or intersecting orbits. Following the fragmentation of a PEGASUS HAPS kick stage and scattering of orbital debris after separation from the payload [2127], it became necessary to make provisions to dump unused propellants at the end of a mission and inert the tanks by exposing them to vacuum. In the case of hydrazine this cannot be done by simply exposing the tank to vacuum because residual hydrazine would freeze and greatly delay the time required to achieve a totally inert stage. Supersaturated hydrazine would help to clear the lines, because the released dissolved pressurant gas will eject the slug of liquid ahead of it like champagne from a suddenly opened bottle that had not been sufficiently cooled.

The geostationary orbit is crowded, and satellites are now spaced closer and closer to each other. A satellite breakup in geostationary orbit would cause significant damage to neighboring satellites and must be avoided by controlled passivation after end-of-life satellites have been moved to a graveyard orbit [320, 2128].

The ACS of the European heavy launcher ARIANE 5 is a hydrazine monopropellant system including two or more bladder tanks pressurized by nitrogen. Depending on the mission, a residual pressure of some 10 to 20 bar with several kg of hydrazine may remain at the end of the mission in the second stage adapter. To avoid any orbital debris generation, the tanks should be vented to space before the stage re-enters [2129].

The slow rate of evaporation and the formation of frozen hydrazine plugs in the plumbing may delay the inerting of tanks in space once they are exposed to vacuum at the end of a mission [2130].

For upper stages, after having delivered their payload to orbit, venting of unused propellant while still in orbit prior to re-entry into the atmosphere would alleviate some of the concerns about propellant toxicity and tank fragmentation [2131]. This process yields a rarefied vapor and droplet field around the final-stage rocket. This computational method was applied to three-dimensional rarefied vapor and droplet plumes arising from discharging in orbit the residual UDMH fuel of a Chinese CZ-4B final-stage rocket and can probably be applied to other propellants as well.

### 7.15 Firefighting Methods

The extinction of hydrazine fires is easy compared to firefighting of other commonly used fuels (gasoline, kerosene) because hydrazine and its derivatives are miscible with water and after enough water is applied, the puddle of liquid becomes non-flammable. In the event of a fire, the area is best flushed with copious amounts of water until the hydrazine is diluted below the fire point concentration (60% hydrazine) (Section 8.3). Open-air burning tests with hydrazine in open pans of 28-, 315-, and 2100-cm<sup>2</sup> surface area showed that 4.7 L of water was consumed per liter of hydrazine to extinguish a hydrazine fire [2132–2136].

Two parts by weight of water per part of Ae-50 will inert an Ae-50 spill against ignition in air [2137]. In a burning Ae-50 pool, the fuel evaporation rate is approximately 49 g s<sup>-1</sup> m<sup>-2</sup>. A well-dispersed flow of water at 100 g s<sup>-1</sup> m<sup>-2</sup> is enough for extinguishing a fire. A tenfold excess of water (10 kg water per kilogram of fuel) is required to inert an Ae-50 spill against hypergolic ignition with NTO. Bromotrifluoromethane (Halon 1301) can be used to inert vapor spaces or to extinguish small fires, but very high BrCF<sub>3</sub> concentrations are required (>7% by volume), and the protection is not long-lasting.

A series of 38 vapor suppression tests with acrylic-modified foam was conducted on spilled hydrazine, MMH, Aerozine-50, and N<sub>2</sub>O<sub>4</sub> in a remote test site in 1985 and 1986 [2138]. The residues of some of the inerting/fire suppression tests were later ignited on purpose (after the foam had collapsed) as a means of hydrazine disposal. An aqueous acetate-acetic acid buffer solution with a gelling agent was tested as a spill control and fire extinguishing agent against small spills or fires of Aerozine-50 and/or NTO [1997]. Firefighting foams can be used for spill containment and ignition prevention of spilled hypergolic propellants.

The problem with approaching and attempting to extinguish a multi-container hydrazine fire is that hydrazine in adjacent containers may become overheated and explode before the first fire can be extinguished [2139]. In the case of a fire burning around hydrazine drums with varying degrees of fullness in a storage shed, the drums were observed to explode one after the other, ejecting the drum tops, but remaining

standing upright. This behavior would speak for storing drums standing upright on their flat ends, rather than storing them sideways. Some storage yard operators prefer storing drums on their sides because it is easier to roll them around and a hand truck is not needed to move them. It may not be advisable to try to extinguish a hydrazine fire if re-ignition must be feared because the extinguished pool of burning liquid cannot be immediately diluted below the flash point. Emphasis should be on cooling and protecting adjacent containers and structures while allowing the one burning drum to burn out if only one drum is on fire. It is easier to clean up a burnt-out drum than to have to treat hydrazine-contaminated water that floods the fire scene. Additional information on the fighting of hydrazine fires is in the chapter “Dimethylhydrazines.”

## 8 Safety Properties of Hydrazine

Handling safety properties of hydrazine, besides toxicity (which is discussed in detail at the end of this chapter), which must be observed and respected, are predominantly flammability and detonability. This section deals with the safety properties of hydrazine and its mixtures. The safety properties of solid hydrazinium salts were already summarized in *Encyclopedia of Oxidizers*, in the chapter “Hydrazinium Salt Oxidizers.” This current section at hand is restricted to conditions that induce the (inadvertent) vapor decomposition or combustion, whereas the more academic discussions of decomposition or combustion mechanism and kinetics under controlled conditions are discussed in Section 4. For detonability, only the limits of detonability and required modes of initiation of hydrazine by itself are discussed here.

Useful summaries of the hazard properties of hydrazines and other rocket propellants have been published by several organizations. The Air Force *Space Propulsion Hazards Manual* is a three-volume series useful for the design of GSE and planning of fueling operations [1887–1889]. Another very useful three-volume series is the *Hazards of Chemical Rockets and Propellants* handbook published by CPIA. Volume 1 deals with safety, health, and the environment [2140], Volume 2 is on solid propellants, and Volume 3 addresses liquid propellants [2141]. NASA WSTF has put together three very practical handbooks, *Ignition and Thermal Hazards of Selected Aerospace Fluids* (including hydrazine, MMH, UDMH, and Ae-50) [2142], *Fire, Explosion, Compatibility, and Safety Hazards of Hydrazine* [1912], and a similar handbook on MMH [2143]. These handbooks were originally published in loose-leaf format in a ring binder and could be updated periodically. Two of them were later also published by AIAA under the aerospace specification series. These handbooks and survey papers, like the comparison study of explosion hazards of hydrazine and MMH in aerospace launch vehicle environments [2144], cite numerous WSTF test reports as references, but most of these cited reports have unfortunately never been deposited with NTIS and are not available to the general public. Hydrazine manufacturers have published summaries of the safety properties of hydrazine [2145].

A good summary of safety considerations for the use of hydrazine and aqueous hydrazine solutions in the chemical process industry where hydrazine is used as an intermediate and reducing agent is provided in [2146]. This publication provides a summary of the hazards of hydrazine and its aqueous solutions and promotes an understanding of the important role dilution plays in increasing the inherent safety of aqueous hydrazine solutions. It is often difficult to determine whether hydrazine is safe and acceptable for a given application, in particular if the process is scaled up, and if so, what concentration range in aqueous solutions may provide an acceptable safety margin and not constitute an environmental risk.

## 8.1 Flammability of Hydrazine

The limits of flammability of combustibles depend on composition, temperature, pressure, mode of initiation, geometry of vapor space, availability of oxygen, and the direction of flame propagation [1607]. It is impossible to discuss all these parameters in detail, mainly because they have not yet been determined in detail for hydrazine and its derivatives. Most of the hydrazine work was done on the limits of flammability in air, but some information is also available for other oxidizing atmospheres (oxygen, nitric oxide, nitrogen dioxide) or in dilution with inerting compounds (nitrogen, heptane, water). Some work has been done on ammonia flammability that may be of interest to the evaluation of fire hazard of hydrazine/ammonia mixtures and of hydrazine decomposition products. For this reason, some of these data are included here. Because the methylhydrazines are more volatile than hydrazine, there is greater concern over forming flammable mixtures with these fuels than with hydrazine itself.

To evaluate the potential fire hazard of hydrazine and hydrazine fuels and compare it to that of better-known fluids already in use (e.g., gasoline, kerosene, hydraulic oil), the following properties are examined: limits of flammability, autoignition temperature, flash point, and minimum required ignition energy. A comparative hazard evaluation must be based on a consistent set of data, all obtained with the same method. The results of flammability or autoignition of the same compound will vary widely depending on the method and the apparatus used. It would be desirable for all investigators to use standardized flammability test methods. Unfortunately, only the flash-point procedure is covered by an ASTM standard (ASTM D98). For the other fire hazard properties, there exist no standard procedures applicable to hydrazine, and the results vary from investigator to investigator, depending on the method used, making a comparison very difficult.

Most data on flammability characteristics of combustible gases and vapors other than hydrazines were obtained by the US Bureau of Mines (USBM) using a setup that has become known as the USBM Flammability Tester. Results obtained with this apparatus are described in the following section.

### 8.1.1 Limits of Flammability of Hydrazine in Air

The apparatus used in early tests on hydrazine flammability was not the standard USBM flammability tester described in [2147] or [1607], but a small-scale modification of this apparatus that was previously used to determine the flammability limits of liquids of low volatility [1408]. Hydrazine has a low volatility and high boiling point compared with other more volatile liquids where flammability is a concern. The problem encountered by experimenters in the determination of flammability limits of high-boiling liquids was condensation. To prevent condensation, the entire system had to be submerged in a heated constant-temperature bath. Whereas a 50-mm-diameter tube 1.5 m long with upward propagation is used in the standard flammability tester, a smaller tube (25 mm in diameter by 0.25 m length) was used for the hydrazine tests. Ignition by a spark between two electrodes occurred at the bottom of the tube, and the flame propagated upward.

The lower limit of hydrazine flammability at 100.7 kPa (758 mm Hg) and 373 K in air was found to be 4.67% by volume [1408]. Unlike other combustibles (e.g., gasoline), hydrazine does not have an upper limit of flammability, and the flammable range extends all the way to 100%. This range can be narrowed by inerting additives, such as nitrogen, water, or heptane, with or by the removal of air. Strangely enough, heptane, itself a flammable vapor, is the most effective additive in narrowing the flammability range of hydrazine, as is discussed in what follows.

The practice of determining limits of flammability at constant temperatures well above the saturation point does not resolve all safety problems with regard to flammability of saturated mixtures in air. The data of interest to a safety engineer are the temperatures above which the saturated vapor in air becomes flammable. Unfortunately, no studies on flammability of hydrazine fuels have been carried out in this mode. In calculating the lower limit temperature, one must assume that the limits of flammability are independent of temperature and use the data obtained at higher temperature (above saturation) in conjunction with a vapor pressure chart. Within the temperature range considered, the limits are indeed almost independent of temperature. Thus the flammable ranges of hydrazine and its methyl derivatives shown in Figure 55 are superimposed on vapor pressure curves, even though the actual flammability testing was conducted at higher temperatures where all propellant was in the vapor state.

The ignition limits of hydrazine/air and MMH/air mixtures at reduced pressures were measured in a 15-cm-diameter 2-L CRES-304 chamber without provisions for stirring the gas-vapor mix [2148–2150]. A 750-mJ spark jumping a 3.2-mm gap was used to initiate the mixtures. As shown in Figure 56, the flammable range narrows as the pressure decreases, until below 4 kPa partial pressure no ignition occurs at any mixture ratio tested. The temperature scale (not a linear scale) on the top of the graph indicates a saturation temperature of pure hydrazine above which enough hydrazine is present in the vapor phase to form flammable mixtures.

Overpressure data from the closed vessel indicated that all mixtures deflagrated rather than detonated. The destruction potential of hydrazine-air explosions would

**Figure 55:** Limits of flammability of hydrazine, UDMH, MMH, and ammonia at atmospheric pressure in saturated and near-saturated vapor/air mixtures. (Reproduced and modified from [1607].)

be more severe if the geometry of the vessel and the mode of initiation allowed a detonation to develop. It is very likely that detonations would have occurred in much larger vessels with a shock-wave initiation from an adjacent detonation chamber filled with acetylene and oxygen.

Based on the NASA WSTF data, the lower limit of flammability of hydrazine in air at 101 kPa and 366.5 K is at 5% by volume [2149]. This compares to a value of 4.67% reported by Scott, Burns, and Lewis [1408]. The lower flammable limit at 311 K was observed to increase from 5.8% to 7.2% if the pressure was lowered from 50 to 6.2 kPa. The upper limit of flammability at 311 K remained at 100% down to a pressure of 2.2 kPa. Substitution of air with oxygen at 101 kPa had a negligible effect on the lower or upper limits of flammability.

Flash-point data by Olin Chemicals (now Lonza-Arch Chemicals-Arxada) indicate that mixtures down to 40%  $N_2H_4$ /60% water are flammable at room temperature.

**Figure 56:** Hydrazine flammability limit in air. (Reproduced and modified from [2148]).

Legend: + Positive Test; O Negative Test (No Ignition).

### 8.1.2 Effect of Partial Pressure on Decomposition Limits (Without Air)

As indicated in the previous section, the flammable range of hydrazine vapor extends all the way to 100% at ambient pressure. At lower pressures, a pressure limit exists below which hydrazine decomposition flames will not propagate. This pressure limit is dependent on the geometry of the test vessel. In a 2.7-cm-diameter, 118-mL-volume Pyrex tube with spark ignition, the lower pressure limit of hydrazine decomposition without air was determined to be 1.59 kPa (12 mm Hg) at 302 K [1408]. Previous authors [1228] had reported a limit at 4.65 kPa (35 mm Hg) in a 3-cm-diameter and 6.64 kPa (50 mm Hg) in a 1.5-cm-diameter tube. Sparks from an automotive ignition coil were used in the first study referenced earlier. It may be assumed that the energy per discharge was well in excess of 2.4 J. No systematic experimental studies have been conducted yet on the ignition energy required to initiate decomposition of hydrazine vapor (Section 8.3.1).

Three different test vessel geometries were used in the USBM study [1408] to determine the eventual participation of excess liquid hydrazine in the decomposition or explosion. A 2.54-cm-diameter tube with an attached mercury pressure gauge had a volume of 180 mL and the spark ignition electrodes could be placed either at the top or bottom. The largest test vessel was a 5-cm-diameter tube with a 7.5-cm base where the electrodes were located. The volume of this tube was approximately 775 mL, and electrodes were always located at the top. The amount of liquid hydrazine placed in the test vessel ranged from 1 mL in the smallest to 25 mL in the intermediate-size container. The 775-mL vessel was always charged with 10 mL liquid hydrazine. The hy-

hydrazine vapor pressure was adjusted by controlling the bath temperature between 300 and 388 K. The vapor pressure was increased after each test. A new tube and a fresh sample were used for each test in the 89-mL category. At 79.9 kPa (600 mm Hg) initial pressure, the entire apparatus and the oil bath were broken by the force of the explosion after the spark was energized. In the 180-mL tube, up to three consecutive tests were sometimes conducted on the same sample. It was not stated whether the decomposition products of the previous test were removed prior to a repetitive test on the same sample. It must be assumed that the vapor phase was diluted by the products of the preceding partial decomposition test. The results of these repetitive tests are thus not very meaningful and were omitted from the summary in Table 77.

**Table 77:** Hydrazine vapor-liquid decomposition tests.

| Test vessel<br>volume | Liquid<br>hydrazine | Initial hydrazine<br>pressure |       | Bath<br>temperature | Direction<br>of propa-<br>gation <sup>a</sup> | Result         |
|-----------------------|---------------------|-------------------------------|-------|---------------------|-----------------------------------------------|----------------|
| cm <sup>3</sup>       | cm <sup>3</sup>     | kPa                           | mm Hg | K                   |                                               |                |
| 89                    | 1                   | 9.7                           | 73    | 331.2               | U                                             | +              |
| 89                    | 1                   | 27.1                          | 203   | 351.7               | U                                             | +              |
| 89                    | 1                   | 53.3                          | 400   | 369.7               | U                                             | +              |
| 89                    | 1                   | 80.0                          | 600   | 380.2               | U                                             | + <sup>b</sup> |

<sup>a</sup> U = upward, D = downward.

<sup>b</sup> Apparatus burst.

Data source: [1408]

As shown in Table 77, the lowest vapor pressure at which vapor decomposition was observed was 2.39 kPa (18 mm Hg) in downward propagation. There was no noticeable difference between tests initiated at the top or at the bottom. In none of the tests would the vapor decomposition initiate decomposition of excess liquid in the glass tube. However, in those tests at initial hydrazine pressures above 80 kPa (600 mm Hg) where the apparatus burst, no liquid hydrazine could be recovered.

The lower decomposition limit of hydrazine was found at 309 K, corresponding to a vapor pressure of 3.17 kPa (23.8 mm Hg) [1216]. However, in the diagram (Figure 57) it is very difficult to explain why, at a given temperature, the decomposition zone narrows with increasing temperature rather than widens as one would expect. The decrease in pressure changes the limits of flammability but does not seem to have a pronounced effect on the flame speed of the decomposition flame. Flame speed and other aspects of decomposition flames will be discussed in Section 4.9.

### 8.1.3 Effect of Diluents on Decomposition Limits of Hydrazine (Without Air)

The upper limit of 100% hydrazine vapor flammability in the absence of air can be lowered by the addition of inert diluents. Inert diluents that have been tested include nitrogen [1216, 1228, 1408], helium [1408], water vapor [1408], argon [1216], hydrogen [1216], and ammonia [1228]. Ammonia was found to be more effective in suppressing hydrazine explosions than nitrogen [1228]. This section discusses the effect of such diluents on the flammable limits of hydrazine vapor decomposition without air. In a later section the effect of diluents on the limits of flammability of hydrazine in air will be discussed.

The hydrazine-nitrogen system has been investigated by several authors. This system is of practical importance over a wide range of pressures and temperatures because during the distillation of anhydrous hydrazine a blanket of nitrogen is often maintained for safety reasons. After the drums or tank cars are filled with hydrazine for shipment, a nitrogen “pad” is also used to fill the ullage space. In the USBM flammability tester in a spark-ignition tube with a 25-mm (1-in.) diameter, the lower limit of

flammability was 38% by volume hydrazine, 62% nitrogen at 383 K, and ambient pressure [1408]. Similar results were obtained with helium as a diluent (37% hydrazine, 63% helium). At lower pressure (total pressure = 24.7 kPa = 185 mm Hg) and lower temperature (373 K) in a 30-mm-diameter glass tube, the limit was found at 48.6% hydrazine [1228]. These limits are shown along the  $N_2$ - $N_2H_4$  side of the triangular chart in Figure 58.

**Figure 58:** Flammability of hydrazine/oxygen/nitrogen mixtures. (Reproduced and modified from [1228] and [1408].)

The water-hydrazine system is also of interest because hydrazine hydrate is being distilled in large amounts in the chemical industry. Furthermore, hydrazine/water mixtures may be formed in the attempt to extinguish hydrazine fires with water. In the USBM tester the lower limit of hydrazine-steam flammability was found at 30.9% by volume (vapor) hydrazine = 44.3% by weight at ambient pressure and 408 K (275 °F). This indicated that under adverse conditions even the vapor of 100 or 85% hydrazine hydrate (64 or 54.4% hydrazine) can still explode (see Figure 61 discussed in the next section).

In a study of the effect of hydrocarbon or aniline vapor on the decomposition of hydrazine vapor initiated by an electric arc, in the absence of any other diluent or air, hydrazine vapor could be ignited at partial pressures above 5.33 kPa (40 mm Hg) [2151]. In the presence of diluents, the partial pressure of hydrazine could be increased above this level without forming flammable mixtures. Of the various compounds evaluated and illustrated in Figure 59, *n*-heptane was the most active inhibitor, whereas benzene and aniline had only a very small effect. These data were measured at 373–393 K in the absence of air.

**Figure 59:** Suppression of decomposition of hydrazine vapor by hydrocarbons or aniline. (Reproduced and modified from [2151].)

In a similar study, the effectiveness of hydrogen, nitrogen, or argon in suppressing the decomposition of hydrazine was studied at different pressures [1216]. Generally, the permanent gases were less effective than the organic compounds shown in Figure 60. The gas data could probably be superimposed on the same chart, but the available data extend to 66.7 kPa (500 mm Hg) instead of 18.7 kPa (140 mm Hg).

Ambient pressure of the mixture is reached as soon as the two partial pressures read from the axes add up to 760 mm Hg. Of the three gases evaluated, hydrogen was found to be the most active inhibitor, but it was not as active as the worst of the organic vapors evaluated in Figure 59.

**Figure 60:** Suppression of hydrazine decomposition by hydrogen, nitrogen, or argon. (Reproduced and modified from [1216].)

It is interesting to note that ignition near the limit in the hydrazine vapor/heptane vapor system at 388 K (239°F) depends on the ignition energy applied to the spark gap [1408]. When more than 7% by volume heptane vapor was mixed with hydrazine vapor, the mixture could not be ignited by the spark from an automotive ignition coil fed with 12-V, 60-cycle AC at 1.7 A. However, when a capacitor of 400  $\mu$ F was charged to 10 kV DC and discharged across the gap, the arc would ignite mixtures with up to 9.1% heptane. A discharge from a 7108- $\mu$ F capacitor array charged to 12 kV would even ignite mixtures containing 13% by volume heptane vapor.

#### 8.1.4 Effect of Diluents on Flammability of Hydrazine in Air

Some of the diluents tested to suppress the combustibility of hydrazine in air were already discussed in Section 8.1.3 with regard to their effectiveness to suppress the vapor-phase decomposition of hydrazine in the absence of air. The diluents tested there included water, nitrogen, and *n*-heptane.

Water is a diluent that may be admixed to the hydrazine itself and form hydrazine hydrate in the liquid state. *n*-Heptane is not miscible with liquid hydrazine, and mixtures exist in the vapor phase only. In addition to the limits of anhydrous hydrazine, the limits of 85% hydrazine hydrate (54.4% hydrazine in water) in air have been determined as well [1408]. At the time when those data were first reported, some uncertainty still existed as to the degree of dissociation of hydrazine hydrate vapor into its constituents:

**Figure 61:** Flammability of hydrazine/water/air mixtures. (Reproduced and modified from [1408].)

Because the hydrazine hydrate was admitted to the apparatus by weight and the air by volume, the flammability limits expressed in percent by volume will depend on the vapor density/dissociation of hydrazine hydrate. In the meantime, more detailed information has become available on the dissociation of hydrazine hydrate in the vapor phase [226] (Section 2.1.9.4). According to these data, hydrazine hydrate is completely dissociated above 350 K. The vapor composition (in percent by volume) at the lower limit of flammability at 373 K is thus 5.95% hydrazine, 8.66% water, and 85.39% air. This lower limit (LL) is shown along the dashed line in Figure 61 from [1408]. This figure shows the extrapolated flammability range in the hydrazine-air-water system.

Except for the data obtained with 85% hydrazine hydrate, no data are available to fill in the center of this ternary diagram. More accurate data are available for the limits in the binary systems hydrazine-water and hydrazine-air shown along the left and right side of the triangle. From these data the approximate course of the flammability borderline can be extrapolated (solid line). Its exact location is dependent on the initial temperature of the flammable mixture; the line shown is for 373 K. At higher

temperatures the flammability range is wider, as is evident from the location of the data point for hydrazine-water at 408 K.

One phenomenon that is not quite understood and also is not sufficiently discussed in the original publication is that of an alleged upper limit of flammability (UL in Figure 61) said to be encountered at 27.4% hydrazine, 39.8% water, and 32.8% air [1408]. It was previously stated that hydrazine itself does not have an upper limit, and the same seems to be true for 85% (by weight) hydrazine hydrate, equivalent to 40.16% by volume hydrazine in the vapor phase. This composition is within the flammable range of the hydrazine-water system in the absence of air. Apparently, mixtures between the upper limit and the air-free composition are only marginally flammable. A third limit has not yet been detected, and additional work in this system may be warranted to clarify the contradictions.

Unfortunately, no accurate data are available on the flammability of the ternary system hydrazine-nitrogen-oxygen. From the two data points available (38% hydrazine/62% nitrogen; 4.67% hydrazine, 75.3% nitrogen and argon, 20.0% oxygen), attempts have been made to extrapolate the borderline in the ternary chart in Figure 58. Until more experimental data become available, this curve should be used with caution.

The hydrazine-heptane-air system has been thoroughly investigated because of the unique ability of heptane vapor to suppress decomposition and combustion of hydrazine vapor. Tests in a 32-mm-diameter tube gave results essentially identical to those obtained with a 50-mm tube. For this reason, all tests were done with a 32-mm-diameter borosilicate glass tube. Of all hydrocarbons investigated, heptane was the most active diluent [2152, 2153]. Cumene, xylene, toluene, and benzene were found to be less active in this respect. Heptane has thus been suggested as a blanketing fluid during hydrazine distillation to prevent the formation of detonable mixtures. Figure 62 shows the flammability limits of the ternary system hydrazine/heptane/air at 398 K. The minimum heptane concentration for flammability suppression is 21% by volume, revised from an earlier questionable finding of 13%.

### 8.1.5 Limits of Flammability of Hydrazine in Other Atmospheres

The explosive decomposition of hydrazine vapor in the absence of oxidizers was first studied in the laboratory in 1939 [1228]. In 15-mm- and 30-mm-diameter quartz vessels with an arc across tungsten electrodes for ignition, the lower limits of explosion were found at 6.66 and 4.66 kPa (50 and 35 mm Hg), respectively.

In the presence of oxidizers, mixtures of hydrazine vapor and other atmospheres may autoignite above a threshold temperature. In other cases, even liquid hydrazine may ignite. Nitrogen dioxide and hydrazine are hypergolic. The autoignition flammability characteristics of hydrazine fuels in dilute NO<sub>2</sub> atmospheres was investigated [2154, 2155]. The technique used was to inject small amounts (70 μL) of fuel into

**Figure 62:** Flammable mixture compositions of hydrazine/heptane/air system at 398 K and atmospheric pressure. (Reproduced and modified from [2153].)

a uniformly heated 250-cm<sup>3</sup> borosilicate glass Erlenmeyer flask containing air and NO<sub>2</sub>. The results for ambient temperature are shown in Figure 63 as a function of NO<sub>2</sub> concentration. Under these conditions, hydrazine itself was more difficult to ignite than methylhydrazines.

With increasing ambient temperature, ignition occurred at lower and lower NO<sub>2</sub> concentrations, as shown in Figure 64 for hydrazine. A similar graph is available for MMH (chapter “Methylhydrazine”). Helium dilution narrows the autoignition range, and pressure increase widens it.

## 8.2 Autoignition Temperature of Hydrazine

The autoignition temperature of a fluid is the minimum temperature at which a combustible fluid with or without an oxidizer (usually air) will spontaneously

**Figure 63:** Minimum spontaneous ignition temperatures of liquid hydrazine, MMH, and UDMH in contact with NO<sub>2</sub>/air mixtures. (Reproduced and modified from [1607].)

ignite and produce a flame. Autoignition temperature depends on the composition and pressure of the combustible vapor and on the type of hot surface present. It also depends on the amount of confinement, whether or not the vessel is vented. Upward propagation in a gravity field will aid ignition. Generally, autoignition tests are conducted at atmospheric pressure and with stoichiometric mixtures.

Because there are many different experimental setups in use, it is very difficult to compare autoignition data from different sources. ASTM methods exist for measurement flash points where a pilot flame is moved over a supply of vapors, but autoignition is a different situation without the use of a pilot flame. The instructions for ASTM E659-78 state, "This method is not designed for evaluating materials which are capable of exothermic decomposition." Hydrazine is capable of exothermic decomposition, and therefore Method E659 is not suitable for determining the autoignition temperature of hydrazine in air. Another method used for determining the self-ignition temperatures of combustible fluids uses the Setchkin apparatus.

**Figure 64:** Minimum spontaneous ignition of liquid hydrazine at various initial temperatures in NO<sub>2</sub>/air mixtures. (Reproduced and modified from [1607].)

### 8.2.1 Autoignition Temperature of Hydrazine in the Presence of Air

In the literature there exist many conflicting data on the autoignition of hydrazine in air. Autoignition temperatures between 438 and 673 K have been reported using glass vessels. Using a Setchkin apparatus and a modified borosilicate glass apparatus, and scanning a temperature range of 448 to 538 K in 10-K increments, the lowest statistically significant (4 ignitions out of 25 tests) ignition occurred at 498 K [2149]. All tests were repeated at least 25 times. The percent ignitions did not increase systematically with the test temperature, as expected.

There was a low incidence of ignitions at an intermediate temperature and a total “outlier” of an isolated ignition event at the lowest temperature tested. These observations cast a shadow of doubt on the accuracy of the data and the adequacy of the method used. One cannot give an exact autoignition temperature for hydrazine in air. At best, one can give a range of temperatures over which ignitions have been observed. A very comprehensive summary of autoignition temperatures of combustible gases and vapors is given in the US Bureau of Mines Bulletin 627 [1607] and other publications by that same organization [2154, 2156]. The dimensions of the uniformly heated apparatus were chosen to be large in relation to the quenching diameter to minimize

wall effects. USBM used two different size vessels for testing, a 0.2-L borosilicate glass flask and a 4.9-L cylindrical steel vessel. The glass flask and the test method used for it were patterned after ASTM-D-2155-63T. The vessel and the oxidizing atmosphere in it were brought to test temperature first, and the test fluid (at room temperature) was injected with a hypodermic syringe. Ignition was determined through a sudden pressure rise recorded by a pressure transducer. At the lower test temperatures, ignition delays could extend to 10 s. The results are summarized in Table 78.

**Table 78:** Autoignition temperatures of hydrazines in air and oxygen at atmospheric pressure.

| Oxidizer<br>Fuel/Vessel | Air         |             | Oxygen      |             |
|-------------------------|-------------|-------------|-------------|-------------|
|                         | Glass 0.2 L | Steel 4.9 L | Glass 0.2 L | Steel 4.9 L |
| Hydrazine               | 543         | 451         | 423         | 371         |
| MMH                     | 457         | 423         | —           | 345         |
| UDMH                    | 525         | 499         | 497         | 457         |

Data source: [2154], all temperatures in K

In addition to data for air and oxygen, intermediate data were obtained for oxygen enriched air with 50 and 70% oxygen. The effect of oxygen enrichment is more pronounced for hydrazine than UDMH. The same two vessels were used to measure the effect of initial pressure on autoignition temperature. The results are summarized in Table 79.

**Table 79:** Autoignition temperatures of hydrazine in air and oxygen as a function of initial pressure (in comparison to those of MMH and UDMH).

| Fuel      | Oxidant | Vessel, L | Lowest observed AIT, K |     |     |     |     |
|-----------|---------|-----------|------------------------|-----|-----|-----|-----|
|           |         |           | 740                    | 400 | 100 | 50  | 25  |

All temperatures in K; data in *italics* are interpolated.

Data source: [2154].

If the logarithm of the test pressure was plotted against the reciprocal absolute temperature of autoignition, a straight linear (Arrhenius-type) relationship could be observed, suitable for data interpolation.

If oxidizer and fuel are pre-mixed first and then heated, the difficulty frequently encountered with autoignition temperature testing is raising of the test temperature uniformly and quickly without triggering premature slow reactions in the gas phase. Some ignition reactions also show an inhibition induction period, causing a delayed ignition only a long time after the test temperature has been reached. This has also been observed with hydrazine or UDMH in closed vessels at low pressures.

The autoignition temperature of hydrazine in air was determined in Pyrex and stainless-steel vessels [1408]. In Pyrex glass the autoignition temperature was 543 K (518 °F) in air and 477 K (397 °F) in oxygen. In stainless steel it was considerably lower, 429 K (312 °F) in air. A catalytic effect of the metal surface cannot be excluded. In the presence of rust or platinum, hydrazine may even ignite at room temperature. When a black iron pipe threaded cap was substituted for the Pyrex flask, ignition occurred at much lower temperatures, 405 K (270 °F) in air. In the presence of Shell 405 catalyst, hydrazine vapors and hydrazine decomposition products in air may ignite at room temperature [2157].

Early ignition tests at NASA WSTF were patterned after ASTM D2155-66 but did not give the desired information about the catalytic contributions of incompatible materials of construction of space vehicle propulsion systems [2158]. The ASTM apparatus was modified and additional instrumentation and a sample holder added to the borosilicate Erlenmeyer flask. At temperatures above the minimum reaction temperature many materials continued to heat up as long as they were exposed to a fresh air supply and repeated injections of hydrazine. The thermal regeneration temperature was defined as the minimum initial specimen temperature, which continually increased when hydrazine was injected into the test flask at a rate of 50  $\mu$ L in 30-s intervals. The lower the thermal regeneration temperature, the less compatible the material was rated for hydrazine service.

A 15.7-cm-diameter and 14.7-cm-high CRES-304 chamber was used to study the pressure dependence of the autoignition temperature of hydrazine in air at 20–100 kPa [2159]. The chamber pressure was adjusted to the desired pressure by evacuation. The chamber was heated prior to injection of the fuel sample. The fuel sample was temperature conditioned to 322 K prior to injection. Photocells, thermocouples, and pressure transducers were used to sense the reaction. The test sequence was such that hydrazine was injected into the test chamber, which had been pre-conditioned. If autoignition occurred, then the same quantity of fuel was injected for a subsequent test at a temperature that was 10 °F lower than before. The process was repeated until the lowest autoignition level for temperature, pressure, and amount of hydrazine injected was verified. In two test series with hydrazines in air at four different pressures, this required 529 individual tests for hydrazine. The ignition delay of hydrazine in air varied from 0.5 to 27 s. The autoignition temperature

of hydrazine decreased from 488 to 400 K when the pressure was increased from 20 to 100 kPa. In most cases, measured overpressure agreed closely with that predicted for a deflagration and was far lower than what would have to be expected if a detonation had occurred. No ignitions were observed at pressures below 6.5 kPa.

The autoignition temperature of 0.03-mL droplets of hydrazine squirted on heated material samples in air showed a marked dependence on the type of materials exposed. Some materials showed more catalytic activity than others. Even the same material gave different autoignition temperatures, depending on the degree of corrosion or other contaminants present [2160]. The materials tested were those that could possibly be exposed in the movable nozzle section of the solid rocket booster of the Space Shuttle. A hydrazine-powered gas generator and gas turbine provided power for a hydraulic pump that pivoted the nozzle for thrust vector control. A hydrazine leak in the vicinity of hot surfaces could theoretically lead to a fire hazard. The following materials caused ignition on contact of liquid hydrazine with the material at  $403 \pm 5$  K: stainless steel 301 corroded in salt spray, stainless steel 301 contaminated with WD-40 lubricants, and D6AC steel corroded by 24-h immersion in seawater. At  $573 \pm 5$  K, ignition occurred on Hastelloy B contaminated with WD-40; at  $503 \pm 5$  K, ignition occurred on Inconel 600 and Pyrex glass. Ignition on Inconel 602 occurred only at much higher temperatures. The following materials were tested at  $403 \pm 5$  K with hydrazine in air, but ignition followed by explosion of vapor did *not* occur: CRES-301, CRES-302, CRES-304L, CRES-316, CRES-321, Ti-3Al-3.5V, Ti-6Al-4V, Inconel 600, Inconel 718, 17-4PH Steel, Al-6061-T6, Al-2219-T87, Al-7075-T73, and glass. Five more materials were tested at 473 K with no ignition: D6AC Steel, Al-2124-T85, PR-1422 Sealant, DC-93-076 Sealant, and Hastelloy B. Materials that caused hydrazine ignition in air were retested in a nitrogen atmosphere, but the nitrogen environment prevented ignition in all the cases where it previously occurred in air. Tests in a carbon dioxide atmosphere were complicated by the premature reaction between hydrazine and  $\text{CO}_2$ , but no explosions occurred.

The autoignition temperatures of many hydrazine mixtures are not known. As expected, the autoignition temperature of 85% hydrazine hydrate was considerably higher than that of anhydrous hydrazine, namely, 565 K (557°F) in air and 491 K (424°F) in oxygen when the Pyrex flask was used [1408].

### 8.2.2 Autoignition Temperature of Hydrazine in Oxidizer-Enriched Air

Hydrazine, MMH, and UDMH have found widespread use as bipropellant fuels with NTO as an oxidizer. These combinations are the most important storable fuels and have been used throughout the GEMINI, APOLLO, and Space Shuttle programs. The Space Shuttle used NTO/MMH for the OMS and the reaction control system. In evaluating the safety of these fuels for manned space flight operations, the minimum spontaneous ignition temperatures in pure air as well as  $\text{NO}_2$ -contaminated air were of interest. Because the composition of the oxidizing atmosphere varies with

temperature and pressure as a result of the  $\text{N}_2\text{O}_4$  dissociation equilibrium, “ $\text{NO}_2$ ” is frequently used to describe the  $\text{NO}_2/\text{N}_2\text{O}_4$  equilibrium mixture. Flammable and self-igniting hydrazine/ $\text{NO}_2$  mixtures in air could result from simultaneous leaks of both the oxidizer and the fuel system.

### 8.2.3 Autodecomposition Temperature of Hydrazine in the Absence of Air

A widely used method for determining the thermal stability of monopropellants and explosives was the ICRPG (later JANNAF) Liquid Propellant Test Method No. 6, which is now an antique [2161]. It used a 2.5-mL bomblet holding a 0.5-mL sample immersed in a molten metal bath (Wood’s metal) pre-heated to 460 K. The bath temperature and the differential temperature between the bath and the propellant sample were recorded in order to detect the onset of exotherms. The results of ICRPG thermal stability tests with hydrazine are summarized in Table 80. Similar data are available for MMH, MHF-5, and MHF-7 (*Encyclopedia of Liquid Fuels*, chapter “Methylhydrazine”).

**Table 80:** ICRPG thermal stability test results for hydrazine (sorted by material name).

| Material    | Exotherm |     | Disk rupture |                 |
|-------------|----------|-----|--------------|-----------------|
|             | K        | °F  | K            | °F              |
| 17-7PH      | 514      | 465 | 553          | 535             |

Source: [2161]

Only the lowest temperature at which exotherms occurred or burst disks ruptured are listed. (The original source showed a range of temperatures.) There was a distinct dependence of the exotherm and disk rupture temperatures on the material from which the bomblets were made. The heating rate was 5.5 K/min. With hydrazines, most of the exotherms began at 505 K and the burst disk ruptured above 533 K. The stability was best in Inconel X or CRES-321 and worst in aluminum. With MMH, the stability was best in Hastelloy X and worst in aluminum. In comparative tests where hydrazine or MMH vapors only were contained in the bomblets, the burst disks ruptured at lower temperatures than in the liquid tests. Rupture occurred at temperatures 55 K below

those measured in the liquid tests. MHF-5 was much less stable than any of the other propellants.

The autodeonation-autodeflagration potential of liquid hydrazine or hydrazine vapor above liquid at saturation temperature was tested in a liquid-phase exothermicity test (LPET) at NASA WSTF [2148, 2162]. The LPET was conducted in a 100-mL CRES-304 chamber with 112 to 116 cm<sup>2</sup> of wetted surface area [2163]. The test chamber was approximately 5 cm in diameter with a wall thickness of 0.5 mm and had fittings on each end to accommodate sample loading, fill and vent lines, and thermocouple instrumentation. The test chamber had a tested burst strength of 11.7 MPa. Air was carefully excluded from these LPETs. The sample container was connected to a helium-pressurized accumulator to maintain quasiisobaric conditions prior to ignition. The accumulator was located above and connected to the test chamber through a 6-mm-O.D. capillary bore steel tubing. Helium was chosen because it has a lower density than hydrazine and would prevent hydrazine vapor from entering the accumulator. The temperature of the sample was raised at the rate of 3 K/min until decomposition or evaporation occurred. The results are summarized in Table 81.

**Table 81:** Hydrazine autodecomposition temperature.

| Pressure                                                              |      | Vaporization temperature | Number of positive tests per total number of tests | Mean explosion temperature |
|-----------------------------------------------------------------------|------|--------------------------|----------------------------------------------------|----------------------------|
| kPa                                                                   | psig | K                        |                                                    | K                          |

Data source: [2148]

Allowing the chamber to become conditioned in hydrazine for 16 h at 394 K raised the decomposition temperature threshold slightly, and there was also more scatter in the data compared to the non-passivated chamber. In another series, various materials of interest to the Space Shuttle program were added to the test chamber prior to testing. Of the 13 materials tested, CRES-304, chromium plating, anodized aluminum, K96 tungsten carbide, Graphitar 86, and pure graphite (658 RC) did not catalyze decomposition sufficiently to result in a catastrophic explosion under the conditions of the test. Tests with Rene 41 nickel and M2 tool steel resulted in high-order reactions, but it

could not be determined whether the reaction started in the vapor phase and whether it involved any liquid.

A vapor-phase exothermicity test (VPET) and an LPET were used at NASA WSTF to test the compatibility of hydrazine vapor or liquid with construction materials at elevated temperature in inert atmospheres [2144, 2164]. The VPET apparatus itself, a 500-mL Pyrex test chamber, was inert to hydrazine at 473 K. An amount of 0.02 mL hydrazine was squirted on flat panel test samples in the chamber, and eventual temperature rises were recorded. After the hydrazine had evaporated and eventually reacted with the sample, the vapor space was purged and the remaining hydrazine amount analyzed. If the metal sample was incompatible with hydrazine, as indicated by an exothermic event, only very little undecomposed hydrazine was remaining.

The LPET consisted of a smaller, 100-mL stainless-steel chamber. The chamber was made from CRES-304L. The liquid level was adjusted such that 112 cm<sup>2</sup> of wall was wetted in each test. The bomb was then pressurized with helium or nitrogen to 2760 kPa (400 psig) to prevent the liquid from evaporating. It appears that early tests [2148, 2163, 2164] used helium, but later tests [1912] used nitrogen. The system could be operated in the adiabatic (well-insulated) mode or with a heat sink attached to maintain isothermal conditions.

The parameter reported in the LPET is the exothermic threshold temperature in the presence of the material under test, the initial temperature at which a runaway decomposition is first seen to occur. This temperature gives an indication of the relative catalytic activity/incompatibility and needs to be compared to the temperature at which the empty chamber by itself would cause hydrazine(s) to decompose. The absolute value of the LPET exotherm temperature is highly system dependent and should not be taken as applicable to all situations. In many cases a temperature range instead of a specific temperature number is given to emphasize the inaccuracy of the data.

Initially, the different types of response of hydrazine or MMH liquid in contact with the material specimens at 473 K were classified into three groups [2148, 2163]:

Type 1 materials showed no detectable reaction. No material in this category could be distinguished from the background heat release rate ( $0.6 \text{ kJ}/1.8 \text{ ks} = 0.33 \text{ J/s}$ ) of the stainless-steel system.

Type 2 materials showed detectable reaction, but passivated, and the rate decreased with time.

Type 3 materials showed a progressive increase in heat release rate, such that the heat release rate would exceed the cooling capacity of the heat sink, and a runaway reaction would result.

Some Type 3 materials were then retested at lower temperature to see how low a temperature would be required to move them to a Type 2 or Type 1 category. In one test series looking at various STS APU materials, 18 materials exhibited no detectable exothermicity, 1 material was marginal, and 13 materials exhibited enough catalytic activity to result in thermal runaway conditions [2163]. The difference between CRES-304 and CRES-304L in columns 1 and 3 of Table 82 is hard to explain.

**Table 82:** LPET results for materials in contact with hydrazine in nitrogen.

(sorted by threshold temperature  $N_2H_4$  in first column)

The presence of a trace amount of carbon should not catalyze the decomposition of hydrazine. It is more likely that the two samples had different surface finishes or different passivation treatments. Later data in column 2 show better agreement. The data in the second column of Table 82 for  $N_2H_4$  are those temperatures where the rate of heat evolution exceeded the detectable threshold of  $55 J s^{-1} m^{-2}$  and the surface: volume ratio was typically  $1.25 cm^{-1}$ . Similar LPET data are available for MMH (chapter “Methylhydrazine”).

For some of the materials in Table 82 additional data obtained with an ARC have become available. For such tests, the activation energy can be measured and the heat generation per unit surface area can be calculated as a function of temperature and presented in graph form, as has been done in the NASA report [1912]. In many instances the acceptability of materials may also depend on the degree of dispersion. Thus, metal samples may be acceptable when tested in bulk, but, ground to a fine powder (e.g., abrasion from sprockets of gear pump) and accumulated in an in-line filter, the same metal may be the cause of instant autodecomposition and gas evolution. When tests with M-2 tool steel (one of the least compatible samples tested) were repeated at higher pressure (6.9 MPa instead of 2.76 MPa), the time to runaway reaction was shortened. This disproves earlier suggestions that one would only have to keep the hydrazine from evaporating to prevent explosions.

The thermal hazard test consisted of a 100-mL CRES-304 chamber installed in an expendable thermally insulated chamber [2164] and eventually evolved into the LPET. Material samples with 112-cm<sup>2</sup> surface area were mounted in the chamber, submersed in 90 mL hydrazine, and heated to 500 K while simultaneously recording pressure and temperature. This setup was very similar to an accelerating rate calorimeter. Several thermal runaway reactions in the chamber resulted in an explosion. With hydrazine alone, an exothermic reaction occurred at 450 K, which produced an initial heat release rate of 1.8 J/s. Raising the temperature to 478 K increased the rate to 5.3 J/s. The apparatus can only detect incompatibilities with materials that are less compatible than CRES-304, the container material. The thermally most unstable material in this test series was A-FM silicon core iron. Anodized aluminum was not much different from the background rate of decomposition. In a group of seven non-metallic materials tested, AF-E-411 and EPT were the most compatible, Kynar was the least compatible polymer. An exothermic reaction between hydrazine and Kynar 460 started between 388 and 413 K and in some instances caused destruction of the test apparatus [1646]. Kalrez 1045, two grades of Tefzel, and FEP Teflon were subsequently evaluated as replacements for Kynar 460 [1722]. With Kalrez 1045, an exothermic reaction was observed as low as 422 K and exothermicity with a sample of dyed Tefzel began even lower at 366 K. It is not known what function the dye had in the polymer. An undyed sample was a little more compatible. It was surprising that Teflon FEP, which is considered to be compatible with hydrazine under most conditions, did also begin to react at 422 K. Microseal 100-1 AMS255 and tungsten carbide were the most reactive seal and valve seat materials.

In most satellites, propellant lines are wrapped with electrical strip heaters to keep the hydrazine from freezing. Malfunction of the temperature controller for the strip heaters leads to a failure mode where the heaters receive full power all the time and overheat the lines and the hydrazine therein. This worst-case condition was simulated in two tests, one using a 23-cm section of heated CRES-321 line with an active thruster connected to its end to study the effects of hot propellant on thruster operation [1173]. Twenty-six tests were conducted with the thruster in different duty cycles

and pre-test soak temperatures from 450 to 538 K (350 to 510 °F). At the higher temperatures, the heated section of the line would dry out and the thruster had to ingest bubbles before it developed full thrust. The hot section of the line slowly filled with decomposition product gases, and the liquid/vapor front recedes to cooler zones. Thruster operation at feed line temperatures up to 538 K was demonstrated without any damage to the thruster or the feed system. The second test, a static test, simulated 53 cm of heated CRES-321 propellant feed line complete with Au/Ni brazed unions. Six test specimens with this L-shaped geometry were two-thirds filled with liquid hydrazine, pressurized with nitrogen (1.03 to 1.37 MPa = 150 to 200 psia), heated for 4 weeks to 394, 463, or 505 K (250, 375, or 450 °F) while the pressure was monitored. The pressure rise rate seemed to obey an Arrhenius-type temperature dependence. Hydrazine and gas space were analyzed at the end of the test. One of the six tubes exploded during the heat-up transient, possibly due to tube contamination. Aside from this event, it is amazing to see that hydrazine can tolerate such abuse and not explode. One would not want to design for this condition, but up to a certain point hydrazine may be forgiving, as long as one stays with small line diameters (<5 mm) and as long as the thruster valve is kept cool by heat-sinking it to a mounting plate with large heat capacity.

Concern about the possible effects of a suspected hydrazine fuel line leak in a satellite prompted a study of the autodecomposition temperature of hydrazine sprayed onto a hot (1200 K = 1700 °F) Hastelloy X plate in a vacuum chamber in the absence of air [2165]. Injection of 6-mL slugs of hydrazine onto the plate in a 2.5-m<sup>3</sup> vacuum chamber evacuated to an initial pressure of 4–8 μm Hg caused the hydrazine to instantly turn into a cloud of snow of hydrazine crystals that slowly sublimed and filled the chamber with hydrazine vapor. The distance between the injector and the plate was initially 10 cm but was decreased to 2.5 cm in later tests. A total of 29 tests were reported. In two tests, the volume of injected liquid was decreased to 5 mL, then to 4 mL hydrazine, with essentially identical results. The spray cooled the hot plate, and, based on ultimate pressure readings in the chamber, it was suggested that hydrazine did not decompose because the ultimate pressure in the vacuum chamber was equal only to that expected for hydrazine vapor. No gas analysis was conducted to prove that theory. If any hydrazine decomposition had occurred, the pressure in the chamber would have had to be higher than that observed. For comparison, the same amount of hydrazine was passed through a catalytic thruster in the vacuum chamber. The resultant vacuum chamber pressure was much higher (12 mm Hg) than after the impingement tests.

Slightly different results were obtained by injecting 4-mL slugs of hydrazine onto a metal plate heated to 1043 to 1073 K in a 128-L vacuum chamber evacuated to 10<sup>-5</sup> mm Hg [2166]. In that test, the injection valve opening time could be varied from 12 to 126 ms, the delay until opening an evacuated sample tank valve varied from 5 to 230 ms, and the sampling valve could be kept open for 100 to 1260 ms. Typically, the sampling valve was kept open for 1000 ms. The gases were analyzed by mass spectrometer, showing ammonia, nitrogen, and hydrogen, but no undecomposed

hydrazine. Hydrazine may have adsorbed to the tank walls or hung up in the sampling system. The pressure rise in the vacuum chamber (with vacuum pumps still running) was 1.3 to 8 mm Hg. Complete vaporization of all hydrazine in a closed system should have increased the pressure to 20 mm Hg and complete decomposition would cause the pressure to go to 40 mm Hg.

Until the 1980s, exothermicity tests had to be conducted in large experimental setups to obtain measurable heat flows. Such large tests could not be conducted in a normal chemistry laboratory and had to be relegated to remotely located hazardous test facilities with concrete walls. This situation changed when the first differential scanning calorimeters and then accelerating rate calorimeters and microcalorimeters became commercially available. These instruments are now found in most energetic materials laboratories and enable investigators to safely conduct rocket propellant exothermicity tests in the comfort of a laboratory. Differential scanning calorimeters and accelerating rate calorimeters have also been used to measure the thermal stability of hydrazinium salts, discussed in *Encyclopedia of Oxidizers*, chapter “Hydrazinium Salt Oxidizers.” The current section deals mostly with the thermal stability of liquids as they affect their safety and hazard properties. The kinetics of hydrazine decomposition reactions are discussed in Section 4. More hazardous, uncontrolled decomposition reactions are those occurring in cook-off and bonfire tests (Section 8.12). Before elaborating to set up an expensive and potentially catastrophic cook-off test, it would be advisable to totally characterize the propellant with DSC and ARC tests. These tests can be conducted in the laboratory and consume less sample. They are standardized by the ASTM E-698-79 *Standard Test Method for Arrhenius Kinetic Constants for Thermally Unstable Materials*.

Prior to using ARC, an attempt was made to obtain thermal stability, kinetic rate, and activation energy data by testing hydrazine or MMH in a differential scanning calorimeter [2167]. The difficulty encountered with all testing of liquid samples in a differential scanning calorimeter is the pressure buildup first due to evaporation and then by decomposition products, which causes conventional sample holders (crimped metal pans, glass vials, capillaries, sometimes called crucibles, although they are no longer crucible-shaped) to bulge, leak, and rupture. ASTM Methods E557 (DTA) and E698 (Arrhenius kinetics) deal with these problems insufficiently, and little progress has been made on the DSC of hydrazine or other monopropellants like those based on hydroxylamine. The internal pressure in the crucibles can be compensated by enclosing the sample and the reference cell in a pressurized enclosure and/or using pressure-resistant crucibles. The increased thermal mass of heavier walls of pressure-resistant crucibles reduces the sensitivity of the method. The first exotherm of hydrazine in a CRES-304 sample holder at a heating rate of 10 K/min. seemed to occur at 370 K

The accelerating rate calorimeter used at NASA WSTF for studying the acceleration of hydrazine decomposition reactions by various materials of construction consisted of a 25-mm-diameter spherical sample holder vessel made of pure titanium weighing approximately 8 g by itself and 30 g with the adapter attached, similar to

an accelerating rate calorimeter. The sample holder was mounted in an insulated heater chamber approximately  $25 \times 25$  cm in size surrounding the sample holder [1574, 1576, 2168]. The heater chamber in turn was enclosed in a heavy-duty steel tank with a flanged lid to contain any shrapnel in case the sample holder exploded. Cartridge heaters increase the chamber temperature incrementally and the thermocouple instrumentation on the sample holder looks for signs of an exothermic reaction. If none is found, the temperature is increased another increment and held at that level isothermally for typically 20 min., after which waiting period the whole heat-wait-heat cycle repeats itself until an exothermic reaction is detected. Once an exothermic reaction is detected, the electric heaters provide just enough heat to maintain a zero temperature difference between the reaction vessel and the walls of the heating jacket. The system is then essentially adiabatic. The minimum detectable exotherm was 0.02 K/min. A pressure transducer can be connected to the neck of the spherical vessel to obtain both temperature and pressure readings of the events in the sample holder. Gas that evolves causing pressure buildup can be analyzed for residual hydrazine and decomposition products after each run. Blank runs were done with hydrazine alone, followed by tests with materials samples and hydrazine. With hydrazine alone, the onset of exotherms was usually near 468 K [1574, 1575]. The metals in powder form were weighed in the sample holder and 0.5 mL hydrazine added in a glove box under nitrogen. With CRES-304L, the heat release rate for the sample holder vessel was proportional to the surface area of the stainless-steel powder added. The heat release rate (expressed as  $\text{J s}^{-1} \text{m}^{-2}$ , where  $\text{m}^{-2}$  is the surface of the sample holder) was proportional to the surface area of the metal sample, when nickel powder, nickel turnings, and nickel foil were inserted into the titanium sphere. Surprisingly, chromium, aluminum, CRES-410L, and CRES-316L had very low catalytic activity, which could not be discerned from the background effect caused by the titanium vessel alone. The catalytic effect of CRES-304L was distinct, but low. When normalized by the surface area, CRES-304L, iron, molybdenum, nickel, and cobalt had increasing catalytic activity in that order (increasing from left to right). Cobalt was the most active metal tested in this series at 353 K. The relative ranking of these metals may depend on surface pretreatment (cleaning, passivating) of the samples. As-received metal powder samples are likely to have substantial oxide coatings which may have catalytic activity.

#### 8.2.4 Autoignition of Hydrazine Solutions

The autodecomposition temperature of liquid hydrazine in the ICRPG test in stainless-steel bombs ( $0.5\text{-cm}^3$  sample heated at  $10^\circ\text{C/min}$ ) was lowered from  $519 \pm 2\text{ K}$  ( $475 \pm 5^\circ\text{F}$ ) to  $402 \pm 4\text{ K}$  ( $265 \pm 10^\circ\text{F}$ ) by the addition of 21.8% hydrazinium azide. The addition of 24.6 or 27.6% hydrazinium azide lowered the autodecomposition temperature of hydrazine to  $408 \pm 2\text{ K}$  ( $275 \pm 5^\circ\text{F}$ ) [141, 142]. In every case the exothermic reactions caused rupture of the burst diaphragm, which was rated for 32.3 MPa (4700 psi) at room temperature.

Mixtures containing 19, 20, or 27% ammonium perchlorate in hydrazine detonated when heated to 437, 433, or 432 K in an ICRPG/JANNAF thermal stability bomb made from stainless steel [2169]. The heating rate was greater than 10 K/min. Propellant-grade hydrazine (without ammonium perchlorate) could be heated to 493 K before the aluminum burst disk ruptured. The hydrazine disk was only bulged and cracked, whereas the perchlorate disks were strongly sheared.

### 8.3 Flash Point of Hydrazine

The “ignitability” or, scientifically more accurately, flash point is determined by heating the liquid in an open cup while moving a pilot flame back and forth over the surface. This test using brass cups is extensively used for the characterization of petroleum products. The Cleveland open-cup method is described in ASTM Method D92-85 and the Tag closed-cup method is described in ASTM Method D56-82. Another Tag open-cup flash point test is described in ASTM Method D1310-86. Because hot hydrazine reacts with brass, a glass insert must be used for hydrazine tests. Occasional puffs of ignition are observed below the flash-point temperature when the pilot flame is moved across the surface, but sustained combustion may or may not occur. The temperature above which sustained combustion occurs is called the fire point. For pure hydrazine, flash point and fire point are identical (324 K = 124 °F), but for hydrazine/water mixtures the fire point may be up to 10 K (18 °F) higher than the flash point (Figure 65).

**Figure 65:** Open-cup flash and fire points for aqueous hydrazine solutions using ASTM-D92 Cleveland open-cup method. (Reproduced and modified from [1645].)

The lowest reported closed-cup flash point for hydrazine in air at 101.3 kPa is 311 K. The open-cup flash point is 324 K [2144]. The TAG closed cup flash point of hydrazine solutions decreased only gently from 359 K at 64% to 352 K at 90%  $\text{N}_2\text{H}_4$ . The flash point of hydrazine is high compared to common combustible liquids such as gasoline (230 K =  $-40^\circ\text{F}$ ) or kerosene JP-4 (259 K =  $7^\circ\text{F}$ ). Despite this, hazardous material transportation regulations (49 CFR 172.101) currently classify anhydrous hydrazine as a flammable liquid (red label). The Cleveland open-cup flash point of hydrazine itself is significantly higher than that of its methyl derivatives, MMH (294 K =  $70^\circ\text{F}$ ) or UDMH (274.2 K =  $34^\circ\text{F}$ ). Both MMH and UDMH are classified as flammable liquids.

The flash point of hydrazine is increased by the addition of water (Figure 65) until above 58% by weight water (below 42% by weight or 40% by volume hydrazine) the mixture can no longer be ignited under any open air conditions, not even with a very hot ignition source. This limit is only a few percent hydrazine above the limit of propagation in an oxygen-free hydrazine-water system.

Temperatures above which ignition can occur in the open-cup test do not agree with those calculated from flammability tests and vapor-pressure curves. The main difference is that the open-cup method is a dynamic method where the liquid is constantly evaporating and mixing with air. In the USBM flammability test apparatus the gases are premixed and static. Furthermore, the vapor in the USBM test must be heated above the boiling point of the liquid to prevent condensation and is thus hotter to start with. Fire extinguishing tests have confirmed that dilution of anhydrous hydrazine with water below 40% by volume hydrazine renders the mixture non-flammable [2132, 2134, 2135].

### 8.3.1 Minimum Required Ignition Energy of Hydrazine

This section covers the energy required to initiate the combustion of hydrazine. A recommended method to measure minimum ignition energies and quenching distances is described in ASTM Method E582-76. Of equal interest as the limits of flammability is the energy required to ignite a flammable mixture of hydrazine and air as a function of composition, temperature, and pressure. Unfortunately, no accurate data are available for any of the hydrazines in air.

The most convenient way to determine ignition energy is by using electric ignition. A high-voltage 60-cycle AC arc from an automotive ignition coil was used for some ignition tests [1408]. Only four tests were conducted with a DC capacitance discharge, for example, a 400- $\mu\text{F}$  or 7.1-mF capacitor charged to 10 or 12 kV, respectively.

Equally few data are available on the minimum ignition energy of hydrazine vapor in the absence of oxygen. Calculated minimum ignition energies for hydrazine vapor decomposition flames showed that for hydrazine vapor at 1 atm pressure and 423 K, the absolute minimum ignition energy lies between 71 and 85 nJ (assuming a prolate ellipsoidal hot pocket with  $a/b = 2$  and a volume equivalent to a sphere radius of 0.033 mm) [1394, 2170]. The computer program in [1394, 2170] allows predictions regardless of

whether an initiation will propagate, depending on electrode gap and vapor temperature. At 345 K, extending the gap from 2 to 4 mm will allow the ignition energy to drop from 1 mJ to below 0.1 mJ. However, at 338 K, extending the gap will only dilute the energy density of the hot pocket, and more energy is required to achieve initiation. At this temperature the minimum ignition energy is 0.9 mJ at an electrode gap of 2 mm.

### 8.3.2 Flammability of Hydrazine Decomposition Products

In addition to the flammability of hydrazine itself, the flammability of its decomposition products in air is of practical interest because sometimes rocket engine or gas generator testing is done at sea-level pressure in closed buildings (test hangars) or the exhaust from vacuum pumps has to be vented to an area free from sources of ignition. The exhaust gas from Space Shuttle APUs was vented to the air during launch and re-entry. The flammability of hydrazine decomposition products depends to a large extent on the degree of ammonia decomposition, that is, on the operating conditions of a hydrazine reactor. No comprehensive study exists on the flammability of these mixtures in air. The simplest case would be  $X = 0$ , with no ammonia decomposition and consequently no hydrogen present. This case can be treated as ammonia flammability with nitrogen diluent. Since ammonia/air mixtures have a narrow range of flammable compositions and are difficult to ignite, the nitrogen dilution will make ignition even less likely. However, with beginning ammonia dissociation and hydrogen formation, mixtures become more flammable and easier to ignite. The limits of flammability and flame speeds in the ternary system hydrogen/ammonia/oxygen have been determined at low pressures, 9.33 kPa = 70 mm Hg and ambient temperature (293 K) [2171]. Similar data are needed for air/hydrogen/ammonia mixtures. If the effects of nitrogen dilution can be quantitatively assessed, some data on combustion in air can be extrapolated from these results. The effect of nitrogen dilution may be like that of lowering the total pressure. The rich limits for the two binary mixtures were at 87.4%  $H_2$  and 70.5%  $NH_3$ , respectively. The lean limits occurred at 4%  $H_2$  and 16.5%  $NH_3$ . At lower pressure (6.66 kPa = 50 mm Hg) the flammable range was a little narrower, for example, lowering the hydrogen upper limit to 81%. The borderlines of flammability followed essentially the lines connecting the pairs of upper or lower binary limits in a ternary diagram, obeying Le Chatelier's mixing rule. The actual flammable range was slightly wider than that predicted by the Le Chatelier rule.

The flame speeds in the ternary diagram showed a decrease from hydrogen to ammonia. The fastest flame ( $S_B = 41.80$  m/s) occurred in a slightly lean 63%  $H_2$ /37%  $O_2$  mixture. With ammonia/oxygen mixtures, the fastest flame speed ( $S_B = 12.50$  m/s) also occurred in a lean mixture (53%  $NH_3$ ). For ternary mixtures, flame speeds fell off on either side of the line joining the two maxima. This line was also running parallel to the stoichiometric line. These flammability and flame speed data are of practical interest where ammonia, dissociated ammonia, or hydrazine exhaust products are mixed with air as oxidizer and used to drive an internal combustion engine or combusted in an afterburner of a ramjet.

## 8.4 Explosive Properties of Hydrazine

The mechanisms that enable the rapid and often very destructive propagation of explosions in energetic substances differ for vapors and condensed (liquid or solid) phases. Therefore, hydrazine explosions in the vapor and condensed state are discussed in separate sections.

This chapter on hydrazine contains two sections dealing with hydrazine detonations. The current section in Section 8.4 deals with detonations of both vapor and liquid hydrazine from a standpoint of safety property evaluation and accident prevention. The other section in Section 4.5.1 deals only with detonations of hydrazine vapor in shock tubes from a more academic point of interest where shock tubes are a useful tool to study kinetics of hydrazine vapor decomposition.

This section on the safety properties of hydrazine deals only with the thresholds and margins under which a detonation may be initiated on purpose. These threshold conditions must be avoided in the design and operation of hydrazine systems in order to prevent accidents.

### 8.4.1 Definition of Deflagration, Explosion, and Detonation

Quite often it is difficult to reconstruct from the remnants of an accident scene whether the cause was a “simple” deflagration or even a detonation. The term *detonation* is reserved for those reactions that obey the Chapman-Jouguet (C-J) equation, in particular high-velocity detonations (HVDs). There is a transitional regime in condensed-phase (mostly liquid) explosives where detonations propagate at lower than maximal velocity, called low-velocity detonation (LVDs). Propagation of LVDs is often aided by inhomogeneities in the detonating medium (bubbles, cavitation, inert granules, micro balloons). An explosion can be caused by either a detonation or a deflagration. Quite often, deflagration-to-detonation transitions (DDT) can be observed in condensed phases or in the gas phase, depending on the geometry of the sample and the amount of confinement.

A deflagration is a flame moving through a flammable mixture at the velocity of a subsonic wave (subsonic with respect to the unburnt mixture). A flame front moves through a mixture confined in a pipe and the pressure rises behind the flame front because combustion products cannot move out of the way fast enough. The increasing pressure behind the flame front will accelerate the propagation from a few meters per second to near sonic velocity in the unburnt mix. Obstacles or constrictions in the path of the flame may cause distortion or dilution with combustion products and cause the flame to slow down or quench altogether. Flame arrestors in ventilation ducts serve this purpose. If the pressure behind a flame front increases rapidly, a deflagration-to-detonation transition can occur. Detonations can also be initiated by a strong source, such as a blasting cap, an electric spark, or a detonation wave of known strength from an adjacent chamber (donor section, a more reproducible method). In a true detona-

tion wave, the chemical reaction coupled to a shock wave travels through the detonable mixture at supersonic speed (relative to the unburned mixture). Since detonations move at supersonic speeds, pressure-sensing devices cannot warn of their coming, and pressure relief valves are too sluggish to respond. In most cases, detonations are quite destructive if the apparatus is not properly designed to confine them.

#### 8.4.2 Vapor-Phase Explosions and Detonations of Hydrazine

The detonation velocity of hydrazine vapor was determined in 20-mm-diameter glass tubes of 3.65-m length at pressures 1.9–101 kPa (14–760 mm Hg) and saturation temperatures from 296 to 387 K (73–236 °F) [2172, 2173]. The glass tubes were held in a steel jacket with observation slots and thermostatted heating mantles. The propagation of the luminescent detonation wave was filmed with a streak camera. Attempts to initiate controlled detonations with a glow plug failed. At 101 kPa only a pale, not very luminescent flame propagating at low speed (50–100 m/s) was observed. Transitions from such a deflagration to detonation occurred only very rarely but are possible. To initiate hydrazine vapor detonations reproducibly, a tube with premixed oxygen-acetylene was attached as a donor section. The detonation velocity at 101 kPa and 387 K was 2360 m/s. At lower pressures it decreased from 2360 to 2270 m/s at 17.7 kPa and 341 K, to 2230 m/s at 7 kPa and 321 K, and eventually to 1980 m/s at 1.9 kPa and 296 K. Below 53 kPa (400 mm Hg) the detonation always propagated as spin detonation. Below 3.3 kPa (25 mm Hg) the spin detonation became unstable and oscillated and pulsed between two different detonation velocities. The spin frequencies also altered abruptly. Such changes were observed to occur approximately every 50–70 cm. The distance between the shock front and beginning luminescence of the reaction front was 6 mm at the lowest pressure and slowest propagation but was much less (below the resolving power of the apparatus) at higher pressures. In some cases, below 3.3 kPa (25 mm Hg) the detonation would simply revert to a deflagration wave.

NASA WSTF in cooperation with McGill University in Montreal, Quebec, Canada, conducted a study of hydrazine vapor detonations in a stainless-steel pipe of 150 mm ID, 7 mm wall thickness, and 1.75 m length [1258]. Detonations of hydrazine vapor were observed at pressures from 120 kPa all the way down to the lowest initial test pressure of 0.5 kPa. The results of these tests and efforts to shore up the experiments with a theory of detonation wave propagation are discussed in detail in Section 4.5.1. For a safety engineer, the most significant and surprising finding is the very low pressure down to which hydrazine vapor continues to be a detonation hazard.

In continuation of the vapor-phase detonation tests at NASA WSTF, detonation cell size, pressure, and velocity for hydrazine vapor and diluent gas mixtures were determined as a function of pressure and hydrazine and diluent concentrations (expressed as vol.-%) [2174]. Tests were conducted in the same horizontal detonation tube heated to 400 K. Hydrazine vapor and diluent gas mixtures and air mixtures were tested at initial pressures of 100, 50, and 10 kPa (14.5, 7.25, and 1.45 psia). Five diluents

were studied: nitrogen, helium, hydrogen, ammonia, and butane. All the diluents, except for helium and butane, are decomposition products of hydrazine and are expected to be present in most decomposing hydrazine systems. Helium, which is used as a pressurant or purge gas in some propulsion systems, could be present in in-flight systems. While the earlier tests used an oxygen/acetylene donor section, mixtures were now initiated using a commercially available blasting cap with an energy output of approximately 1735 J. Detonation velocities and pressures were measured using high-speed piezoelectric pressure transducers. Detonation cells were measured using the smoked-foil technique described earlier. It was concluded that the relative ranking of diluents correlates to the ratio of specific heats ( $C_p/C_v = \gamma$ ). Diluents with a high  $\gamma$  such as helium required a much higher concentration to prevent a detonation of the hydrazine vapor than diluents with a low  $\gamma$  such as butane. For instance, hydrazine vapors required dilution with at least 80% helium to become non-detonable, but only 10% butane would do the same job. The go-no go boundaries were bracketed by obtaining at least three positive and three negative tests on either side of the boundary. The detonation tube was 150 mm (6 in.) diameter and 2.4 m (6 ft) long. Excessive air-hydrazine interaction prior to firing a detonator made the air/hydrazine results very questionable. By the time the temperature had equilibrated in the chamber, most of the oxygen had already been consumed and the air boundaries were very similar to the nitrogen boundaries.

The detonation characteristics of hydrazine vapor have been compared to those of oxygen/hydrazine, oxygen/hydrogen, and other combustible mixtures [1259]. Hydrazine vapor detonations had the lowest cell diameter, along with oxygen/ethylene mixtures. Hydrazine vapor/ammonia mixtures containing less than 74% hydrazine could not be detonated [2175].

The hazard potential associated with hydrazine vapor has prevented thorough studies of the critical diameter of detonation propagation, and minimum ignition energy up to this time. Likewise, data on the effect of water addition on the vapor-phase detonation velocity and pressure-temperature threshold of detonability could not be found.

Hydrazine vapors are explosive even in mixtures with water and residual acetone. Bare steam coils at 533 K can initiate a hydrazine vapor decomposition explosion in a distillation column [1917]. The resulting decomposition dislodged all trays in the column but did no damage to the shell.

#### 8.4.3 Condensed-Phase Explosions and Detonations with Hydrazine

Many of the proposed and actual uses of hydrazines are in immediate proximity to explosive actuators for explosion-operated valves or for separation of rocket stages. As with any energetic fluid or solid, the energy content of hydrazine blends can be increased only up to a certain limit. If that limit is exceeded, the material becomes detonable. This is vividly illustrated by the change in detonability resulting from the addi-

tion of HN to hydrazine. Quite frequently the scale effect is overlooked in determining the detonability of energetic compounds and mixtures. For instance, a hydrazine/hydrazinium nitrate mixture may not be detonable in a 25-mm tube but may become detonable when stored in bulk quantities in 55-gal barrels.

#### 8.4.3.1 Detonability of Liquid or Frozen Hydrazine

The kinetics and fluid dynamics of reactions enabling the propagation of a detonation wave in hydrazine vapor or hydrazine liquid have been summarized in Section 4.5 along with other modes of decomposition of hydrazine. There is some overlap between these two sections. If the publications referenced here have the words *compression* or *adiabatic* in the title, they may be cited in both locations. If the publications deal with the propagation of shock waves in detonable media, they have been referenced in Section 4.4, including references such as [1266–1270].

Attempts at USBM to determine the detonability of liquid hydrazine by means of the Mettengang recorder were not successful because the material is not detonable [1408]. One test in ambient conditions in a steel tube, one test in ambient conditions in a polystyrene tube, and two tests in steel tubes at 378 K were all negative. A comparison test was made in a steel tube filled with water instead of hydrazine. The amount of damage by the army special blasting caps (a significantly stronger detonator than the standard No. 8 cap) to the steel tube was identical for water and hydrazine. The tube geometry was 18.5 cm (7.25 in.) long with a diameter of 2.2 cm (0.87 in.). The wall thickness of the stainless-steel tubes was 1.6 mm (0.0625 in.), but the ends of the tubes were not sealed hermetically. It may be that hot liquid hydrazine when initiated in confinement would exhibit more destructive force than in the unconfined stoppered tube test conducted at USBM.

The USBM liquid-phase detonability tests were repeated by other investigators with essentially identical results [2176]. Liquid hydrazine contained in a 15-mm-diameter, 0.3-mm-wall-thickness aluminum tube could not be detonated by an ordinary (“Briska”) detonator. Another sample in a 16-mm-diameter, 2-mm-wall steel tube would not even detonate if it was boosted by 20 g of NPMn95/5 (a mixture of 95% PETN and 5% mononitronaphthalene).

When liquid hydrazine was passed through heated tube sections to determine the maximum heat flux before burnout, frequent explosions were observed [283]. Based on high-speed cinematography, the tube would fail within less than 5 ms. It has been suspected that liquid hydrazine may have participated in these explosions, but no conclusive proof could be offered. The detonation of the vapor bubble in the boiling film may have been sufficiently powerful to rupture the tube.

Other tests of detonability of hot hydrazine, MMH, and MHF-5 in 20-cm (8-in.) × 2.2-cm (0.9-in.)-ID tubes showed that none of the three fuels will propagate a detonation [2161]. Testing was done in tubes made from CRES-304, -316, -347, Inconel X, Haynes-25, and Hastelloy X to study the contributions of container materials to detonability at 422–477 K (300–400 °F). There was no dependence of

detonability on container material because all tests were negative. Initiation was with a 50-g pentolite booster. In one test with hydrazine in CRES-304L at 477 K, the tube fragmented into large pieces. The test was then repeated with a longer, 76-cm (30-in.) tube, but no propagation occurred. In another case, a hydrazine-filled CRES-304 tube exploded at 490 K (422 °F) before the detonator could be activated. In total, 16 tests with hydrazine, 7 with MHF-5, and 4 with MMH at elevated temperatures were all negative. In a subsequent test series, liquid preheated hydrazine was pushed into an even hotter dead-ended tube simulating the hot restart of a hydrazine engine. In this case, a dependence of sensitivity on the material of construction was noted. It has been shown that 373 K (212 °F) hot hydrazine pushed into CRES-304L tubes will explode if the tube is hotter than 560 K (550 °F). In 17-7PH, hydrazine will begin to explode even at 500 K (442 °F).

Some of the early experimenters may have used poor-quality hydrazine in their detonability tests. Water and aniline as diluents and inhibitors might desensitize hydrazine. There was concern that the high-purity hydrazine used as monopropellant in most spacecraft may be more sensitive than the water-containing hydrazine used by early experimenters. In earlier tests [2177], the hydrazine contained 4% water. Hydrazine used by USBM was only 98% with the composition of the remaining 2% unknown [1408]. It marked an improvement in hydrazine quality control when MIL-P-26536D monopropellant-grade hydrazine was used for liquid hydrazine detonability tests at NASA WSTF [2178]. That specification at the time of these tests allowed up to 1% water. Two series of detonability tests were conducted, one in CRES-304 tubing with 13-mm (0.5-in.) OD and 0.89-mm (0.035-in.) wall thickness in lengths of 25.4, 50.8, and 76.2 cm (10, 20, and 30 in.), the other in a modified card-gap apparatus using 300-series steel tubes (5.08 cm [2.0 in.] ID, 0.55 cm [0.218 in.] wall thickness, 30.48 cm [12 in.] length) welded to a 0.95-cm (0.375-in.)-thick witness plate. In the 13-mm-diameter tube test, the donor charge was taped to the bottom of the tube, separated from the hydrazine by a Teflon foil. In the modified card gap test, the donor charge consisting of 223 g of C-4 was inserted on top of the hydrazine sample. In none of the tests, neither in the 13-mm nor in the 6-cm-OD tube, was there any indication of hydrazine undergoing a detonation. The amount of damage to the tubes was like that observed in control tests with water [2179]. Sensitized liquid hydrazine detonation studies where hydrazine was mixed with gas bubbles and micro balloons did not result in any condensed-phase detonations either [2180].

There are several hydrodynamic codes used for the prediction of detonation properties of explosives. One of the most frequently computer programs is that based on the BKW EOS described by Mader [2181]. The program was available on a CD-ROM disc attached to one of the editions of his book. Mader used hydrazine and HN as textbook examples and sample cases to demonstrate the capabilities of this program. This program was used to calculate detonation and shock Hugoniot wave properties of liquid hydrazine [1266–1268].

An attempt was made to calculate the parameters of the shock compression of liquid hydrazine within the framework of schemes developed for describing the compression of organic liquids and liquefied gases. In cases where the mass velocities behind shock fronts do not exceed  $3.1 \text{ mm}/\mu\text{s}$ , it may be implemented under the assumption of brief retention of the initial compound (hydrazine, in our case) behind a shock front [1274]. The detonation velocities of hydrazine solutions spiked with such explosives as nitromethane and hydrazine nitrate correspond to the destruction of hydrazine up to ammonia and nitrogen, which is accompanied by a noticeable energy release. The estimates performed demonstrated the possibility of the detonation of liquid hydrazine with a velocity of  $8 \text{ mm}/\mu\text{s}$ , during which the heating of the substance behind a shock front (approximately 2000 K) is comparable to those observed behind a shock front during the detonation of liquid explosives [1272, 1273]. The detonation of hydrazine solutions with added explosives (nitromethane or HN) transforms the hydrazine to ammonia and nitrogen with the release of a significant amount of energy [1271]. It is possible to detonate liquid hydrazine at a velocity of  $8 \text{ mm}/\mu\text{s}$  by heating the substance behind the shock wave to  $\sim 2000 \text{ K}$ . The activation energy of hydrazine decomposition is  $222.6 \text{ kJ/mol}$  ( $53.2 \text{ kcal/mol}$ ) (which is a factor of 1.4 higher than the activation energy of other liquid explosives) with large critical diameters ( $>1 \text{ m}$ ) of detonation.

NASA WSTF simulated conditions suspected to lead to the failure of an ATLAS-CENTAUR upper stage which uses liquid oxygen and liquid hydrogen as its main propellants and hydrazine for roll control and propellant settling maneuvers [2182, 2183]. It was suspected that frozen oxygen or frozen hydrazine had formed in a groove adjacent to the interstage adapter ring and was initiated to detonation by firing the adjacent flexible linear shaped charge which is done for stage separation. Tests were conducted with frozen oxygen or frozen hydrazine in a vacuum chamber at 20 Pa and the energy release was measured with a ballistic pendulum. Hydrazine froze readily and formed stalagmites in the catch basin below the leak. Some augmentation was noted with frozen oxygen or but only slight augmentation with frozen hydrazine. A mixture of frozen oxygen and frozen hydrazine was not tested.

#### 8.4.3.2 Detonability of Hydrazine Mixtures

There are many hydrazine mixtures besides the well-studied hydrazinium nitrate/hydrazine/water system that are detonable. Many of these have been considered or patented or actually commercially used as liquid explosives.

### 8.5 Drop-Weight and Bullet Impact Sensitivity of Hydrazine

The sensitivity of energetic compounds can be determined by dropping a weight on it, dropping the entire container from a predetermined height (typically  $12.16 \text{ m} = 40 \text{ ft}$ ), or by impacting it with a projectile.

### 8.5.1 Drop Weight Impact Sensitivity of Hydrazine

In 10 consecutive identical trials where a 5-kg weight was dropped from 1 m onto a one-drop sample of anhydrous hydrazine or 85% hydrazine hydrate, no explosions could be observed [1408]. The USBM drop-weight tester was modified, and no brass cups were used in this test. Instead, the sample was held in a depression in the anvil. Five negative tests out of five with a 5-kg weight from 3 m and one droplet of liquid hydrazine contained in a Bourges capsule showed that the material is not impact shock sensitive [2176].

### 8.5.2 Bullet Impact Sensitivity of Hydrazine

In rifle bullet impact tests, *n*-propyl nitrate, which was tested as a baseline material for comparison, exploded with all three types of ammunition used (20 mm incendiary, 20 mm high-explosive incendiary, and .30 caliber rifle) [2184]. In contrast, hydrazine and alkylhydrazine/24 HN/10 H<sub>2</sub>O monopropellant in 25% or 95% filled 3.78-L (1-gal) aluminum containers were exploded by high-explosive ammunition only, but not by the incendiary type or the .30 caliber rifle bullets. *n*-Propyl nitrate (and presumably also IPN) would be more hazardous as a propellant in a military battlefield situation where bullet impact must be anticipated. In other projectile impact tests, hydrazine and UDMH were shot at while stored in aluminum, stainless-steel, or titanium tanks [2185]. The stainless-steel tank was made from 89-mm (3.5-in.)-diameter tubing by welding on end caps and a similar aluminum tank was made from 102-mm (4-in.)-diameter tubing. The thickness of the end caps where the impact occurred was 0.8 mm (0.031 in.) for both tests. Steel spheres (5.6 mm = 0.219 in.) were accelerated to 1763 m/s and aimed at the end caps. No reaction was observed between the hydrazines and the tank wall in any of the tests, in contrast to liquid oxygen, which started a violent reaction in all materials tested and perforated by bullets.

### 8.5.3 Hypervelocity Projectile Impact Sensitivity of Hydrazine

The HAPS fragmentation event demonstrated the importance of passivating spacecraft and upper stages at the end of missions by draining all propellants from the tanks [2186, 2187]. It is not certain what caused the breakup of the tank after 25 months in orbit, but the impact of a piece of orbital debris is one explanation for the catastrophic event [2127]. After this event, federal authorities at the Federal Aviation Administration temporarily suspended the launch license for PEGASUS XL until OSC agreed that spent HAPS stages should be de-orbited or operated to full exhaustion of all propellant.

The ACS of the European heavy launcher ARIANE 5 is a hydrazine monopropellant system that includes two or more bladder tanks pressurized by nitrogen. Depending on the mission, a residual pressure of some 10 to 20 bar with several kilograms of hydrazine may remain at the end of the mission in the second stage adapter. In order to avoid any orbital debris generation, the explosion threshold pressure was determined

theoretically, then demonstrated experimentally [2129]. This pressure is defined by the behavior of the tank under the impact of a micrometeoroid or a piece of space debris: for pressures above it, the tank explodes; otherwise, it is simply punctured. A theoretical analysis based on fracture mechanics showed that the crack propagation would become divergent for pressures in the range of 20 to 25 bar. A worst case was determined, and a test was performed with a tank pressurized at 18 bar. The impacting particle was a 1-mm-diameter aluminum sphere, launched at a velocity of 9 km/s. The tank did not explode, and the size of the resulting hole was close to the one predicted (3.2 mm in diameter vs. 3 to 3.5 predicted).

Reactive molecular dynamics was used to estimate the risk of detonation in a liquid hydrazine layer. This calculation used the ReaxFF force field and the MD-solver LAMMPS to follow shock compression and decomposition of liquid hydrazine. The force field was initially developed for nitramine explosives but has been successfully applied to hydrazine [1373]. Simulations of a 3.5-mm aluminum spherical debris particle at a velocity of 14 km/s relative to a hydrazine tank showed that the degree of damage was strongly dependent on tank temperature and, hence, on the satellite thermal configuration at its end of life. The sample case was calculated for a typical hydrazine monopropellant propulsion system with a 50-cm-diameter titanium diaphragm tank and typical end of life residuals stored at 5 bar and 293 K (20 °C), including hydrazine vapor detonation initiated by the penetrating projectile.

A computational model for estimating the effect of hypervelocity impact from orbital debris particles on non-shielded propellant and pressurant tanks was based on Eulerian hydrocode and developed to model, first, penetration and shock wave formation in the propellant and, second, subsequent detonation wave propagation and interaction with the tank wall [2188].

## 8.6 Cap Sensitivity and Card Gap Sensitivity of Hydrazine

Card gap tests of hydrazine, hydrazine hydrate, or UDMH in heavy-walled (13-mm = 0.52-in. wall) stainless-steel tubes using two 50-g tetryl pellets as booster were negative, even at pre-test temperatures only a few degrees apart from the boiling points of the liquids [2189].

The results of zero-attenuation detonability tests in the  $\text{N}_2\text{H}_4/\text{HN}/\text{H}_2\text{O}$  system by Dwiggins and Larrick [2177] were confirmed in later tests [244]. The objective of these tests was to look for the possibility of LVD propagation in  $\text{N}_2\text{H}_4/\text{HN}/\text{H}_2\text{O}$  mixtures, which was considered an added hazard when handling bulk quantities of such propellants. Under the conditions tested at SRI, none of the mixtures containing up to 26% HN exhibited LVD. In addition to the standard 50-g tetryl charge for card gap tests, several shots were conducted with doubled booster charges of 100 g tetryl. Some tests were also done at elevated temperature and/or pressure. The results are summarized in Tables 83 and 84.

**Table 83:** Gap test results at 297 K (24 °C) on hydrazine/hydrazinium nitrate/water mixtures.

| Mixture<br>H/HN/H <sub>2</sub> O | HVD Tests          |                |        |                    |                |        | LVD Tests          |                |        |

I.D. = inner diameter

Data source: [244]

HVD tests were conducted in 2.54-cm (1-in.)-diameter, 7.5 cm (3 in.) long tubes, whereas LVD tests used narrower (1.27-cm = 0.5-in.) and longer (10-cm = 4-in.) tubes with thinner witness plates. In agreement with earlier reports [2177], the 24% HN mixture at one card was negative, whereas the 26% HN mixture at zero cards was positive with the standard JANNAF booster size. However, when the booster size was doubled, even the 24% HN mixture was made to go at zero cards in the wider tube but failed to propagate in the narrower tube. The same was true of the  $71\text{N}_2\text{H}_4/24\text{HN}/5\text{H}_2\text{O}$  mixture. In steel confinement and pressurized to 3.44 MPa (500 psig), the  $24\text{HN}/76\text{N}_2\text{H}_4$  mixture did not detonate with either the 50-g or the 100-g tetryl booster, not even at higher temperature (322 K).

In summary, only the mixtures containing 26% HN were initiated to HVD and then only with a gap of less than 10 cards. Nitromethane, a liquid considered relatively insensitive and at one time shipped in tank cars (prior to several severe LVD accidents), has a card sensitivity of positive at 19 cards under these same conditions. Mixtures with more than 26% HN may well exhibit LVD, but this regime was not retested. The SRI tests essentially confirmed the validity of the boundary line as drawn in *Encyclopedia of Oxidizers*, in the chapter “Hydrazinium Salt Oxidizers,” Figure 14.

When evaluating initially non-detonable  $\text{N}_2\text{H}_4/\text{N}_2\text{H}_5\text{NO}_3/\text{H}_2\text{O}$  mixtures as rocket or gas generator propellants, one must keep in mind that under adverse conditions of a spill or leak at high ambient temperatures and low ambient relative humidity the residue may become more concentrated in HN and reach detonable concentrations [2190]. The mixture may also absorb water from atmospheric moisture and carbon dioxide and neutralize itself. Even if the HN concentration in the residue should rise to the detonable level (25 to 30%), there must be a very energetic source of ignition (e.g., detonator with 50-g tetryl booster) before a detonation hazard exists. The booster itself would already cause a significant amount of damage without HN present. At concentrations beyond 40% HN, the mixture becomes shock sensitive to impact. The concern about inadvertent enrichment of HN by evaporative loss of one of the propellant components is more prevalent with ternary propellants of the MHF-5 type, which contain MMH, HN, and hydrazine. MMH is more volatile than hydrazine, and the composition of MHF-5 monopropellant is more likely to change than that of ternary propellants of the HPB-1808 or HPB-2107 type.

## 8.7 Explosive Yield Tests with Hydrazine

Several methods exist for measuring the explosive yield of explosives. The most popular test is the Trauzl block test, where a sample of explosive is detonated in a cavity in a lead block and the enlargement of the cavity is measured by filling it with water before and after the test. Other methods, widely used by the military in measuring the yield of weapons, measure the overpressure of a shock wave propagating through air

at a safe (safe for the pressure gauge, not for the human observer) distance from the event.

The Trauzl block (= lead block) test is not a sensitivity test, but a performance test. Lead block tests of explosives and suspected explosives with PETN or picric acid as booster showed that the utilization coefficient was 69–84 for liquid hydrazine compared to 94 for TNT [2176]. Ballistic mortar tests gave only very scattered results. Medard concluded that some hydrazine decomposed in these tests, but it did not detonate.

The explosive yield as measured by the increase of cavity volumes in lead blocks depends on the mixture ratio of hydrazinium(1+) nitrate (HN) oxidizer and hydrazine fuel. The heat of explosion increases with increasing HN content. The explosive yield as the product of heat of explosion and the amount of gas produced thus remains constant over a wide range of compositions [2191]. The lead block volume as a function of composition maximum is wider than what is commonly observed with carbon/oxidizer-based explosives. Maximum Trauzl block indentations were obtained with  $\text{N}_2\text{H}_4/\text{N}_2\text{H}_5\text{NO}_3$  mixtures away from the stoichiometric composition. The cavity volume increased from 370 to a maximum of  $430\text{ cm}^3$  by increasing the HN content from 40 to 60%. Beyond 60% HN, the lead block cavity volume dropped back to  $340\text{ cm}^3$  at 100% HN. Similar mixtures with hydrazinium(1+) perchlorate achieved higher maximum indentations,  $470\text{ cm}^3$  instead of  $430\text{ cm}^3$ .

In another test series, using 2-mL samples in a lead block made from a 6-mm (0.25-in.) hole drilled into a cylinder 90 mm (3.5 in.) in diameter by 178 mm (7 in.) in length, Trauzl block indentations were measured for 16 hydrazine/hydrazinium nitrate/water mixtures with 15–50% HN and 3–10% water [242]. Initiation was achieved with a Hercules Mark 35 Mod 1 blasting cap. For comparison, the data in Table 85 also show results obtained with 0.5 and 1 g of TNT as a baseline.

## 8.8 Rapid (Adiabatic) Compression Sensitivity of Hydrazine

Most other monopropellants, organic nitro compounds and nitrate esters, are known to be sensitive to adiabatic compression. With those compounds, the sudden temperature increase in a collapsing bubble is enough to initiate detonation and, at the same time, provides a mechanism for propagation of low-velocity detonation (LVD) throughout the sample. A monopropellant of that type that has not been thoroughly degassed or is even filled with bubbles from transportation vibrations/sloshing or transfer from one container to another will propagate LVD once a source of initiation is present. In contrast, liquid bubble-free bulk hydrazine could not be initiated to detonation by rapid or adiabatic compression. However, hydrazine vapor (inevitably present above the liquid phase during high-temperature tests) may detonate when compressed at high rates. Under most practical conditions it will be difficult to elim-

**Table 85:** Trauzl block test data.

inate contributions by hydrazine vapor bubbles when hydrazine is compressed suddenly, in particular in two-phase systems.

Rapid pressurization may occur when hydrazine flows (is dropped into) into initially empty, evacuated propellant distribution lines. Rapid pressurization may also occur in a two-phase system when the flow of liquid hydrazine is suddenly stopped by closing a valve, but the momentum of the flowing liquid continues to compress the liquid/vapor/gas mixture (“water hammer”). There have been incidents where rapid pressurization of hydrazine has caused rupturing of injector passages in STS APU gas generators and rupturing of system manifold lines in ground tests of satellite flight systems. This phenomenon was at one time called adiabatic compression detonation, but in recognition of the fact that substantial amounts of heat are lost to the walls of the apparatus and that the test methods are really non-adiabatic, other investigators called it rapid compression detonation. Some investigators question whether a full-blown detonation can develop in narrow tubes and refer to it as rapid compression deflagration or rapid compression thermal runaway reaction. Regardless of what it is

called, the end result can be very destructive. The problem has been thoroughly researched (mostly by NASA WSTF), and there are many reports on rapid compression of hydrazine. Occasionally the same equipment used for hydrazine rapid compression tests was also used for MMH tests, and there is sporadic mention of MMH in the context of rapid compression and vapor detonations. What is lacking is a computer model that, once provided with the geometry of the propellant manifold, the operating conditions (temperature, manifold fill gas, manifold fill pressure, feed pressure) will predict whether or not rapid compression deflagration of hydrazine is likely to occur. Several hydrodynamic computer models will predict water hammer or surge pressure, but none will raise a red flag if the conditions approach pressurization rates and bubble temperatures/froth conditions under which explosions have been observed. These computer models have been verified using water as the test fluid. Water hammer pressures can create sudden pressure spikes even in water that are sufficiently energetic to rupture burst discs, filters, or damage valve seats and pressure transducer membranes. This can happen, as the name implies, even with non-reactive fluids like water. Because hydrazine has a lower compressibility than water, water hammer or, rather, “hydrazine hammer” pressure spikes are more severe than those observed in model tests with water. In addition to purely hydraulic damage, hydrazine froth can decompose under adverse conditions and cause additional, sometimes destructive, pressure spikes.

This problem is not unique to hydrazine monopropellant systems and would occur regardless of whether a monopropellant or bipropellant thruster was connected to the exit end of the propellant supply line. Because this problem is not unique to monopropellant systems, and because we did not want to repeat the discussion of this topic in future sets of *Encyclopedia of Rocket Propellants*, the effects of surge flow and water hammer pressure spikes are summarized here in *Encyclopedia of Liquid Fuels*.

Many publications do not make a sharp distinction between water hammer and surge flow. A water hammer would compress bubbles in recessed areas as a flowing column of liquid comes to a sudden stop (e.g., by abruptly closing a valve in a system that is already mostly filled with hydrazine). Surge flow occurs when an initially empty or gas-filled manifold is filled with propellant for the first time and the liquid column runs into a dead-ended cavity, compressing the contents of the cavity ahead of it. Either situation can cause very high-pressure spikes because the compressibility of hydrazine is only half that of water.

The rapid compression sensitivity of monopropellants has often been called adiabatic or isentropic compression sensitivity. Truly adiabatic conditions can only be achieved in theoretical model calculations. Under real-world conditions, the walls of the apparatus in which the rapid compression experiment is conducted will absorb part of the energy, and then it is no longer truly adiabatic. In recognition of the adiabatic losses, which depend on the surface:volume ratio and the materials of construction of the apparatus, this property is more accurately called rapid compression sensitivity.

### 8.8.1 Rapid (Adiabatic) Compression Test Methods

The results of rapid compression testing with hydrazine differ substantially depending on the test apparatus used. Several test techniques have evolved over the course of years, and there is no generally accepted test method that serves all foreseeable hazard conditions equally well. The following sections and data in Table 86 are a brief summary of test methods that have been used for rapid compression testing of hydrazine propellants and other energetic liquids at one time or another. Unfortunately, the results from these different tests do not correlate very well, and in some cases the only way to obtain a definitive answer is to test a replica of the actual satellite manifold underground conditions, in particular if additional energy inputs have to be considered such as blow-by of hot gases from pyrotechnic valves.

**Hydrazine Rapid (“Adiabatic”) Compression Sensitivity Fundamentals.** The phenomenon of hydrazine rapid (“adiabatic”) compression sensitivity is still not quite understood despite all the effort that has gone into understanding it over a period of 25 years. Many publications on hydrazine rapid (“adiabatic”) compression sensitivity have been released by various authors, but nobody has ever attempted to arrange the sometimes conflicting test results in a systematic fashion. The difficulty arises from the different experimental techniques used at different times and at different organizations. Even the atmospheric pressure at the test site can influence the results, with experiments at high-altitude locations giving different results from those conducted at sea level. Standardization (using an ASTM standard test method) was once attempted, but without success.

The difficulty in arriving at a clear yes or no answer when applying the experience database to a given spacecraft design and manifold filling procedure is due to the large number of variables that can affect rapid compression initiation thresholds with hydrazine. The results of rapid compression tests with hydrazine may be influenced by the following factors:

- Compression ratio
- Rate of pressurization
- Initial downstream system (= “cavity”) pressure
- Propellant feed pressure
- Feed system line diameter
- Cavity diameter
- Wall thickness of cavity
- Pre-test separation between hydrazine and cavity (none, ball valve, pyro valve, burst disk, Teflon foil)
- Initial cavity fill gas or vacuum
- Presence of condensable vapors (water, cleaning solvents) in cavity
- Initial propellant temperature
- Initial hardware temperature
- Degree of gas saturation of propellant
- Type of gas propellant is saturated with

- Surface : volume ratio at dead end of cavity
- Number of flow obstacles (orifices, tees, ells, viscojets, filters, valves, reducing nipples) in feed lines
- Number of flow obstacles (orifices, tees, ells, viscojets, filters, valves, reducing nipples) in cavity
- Purity of hydrazine propellant (aniline, water)
- Resonant effects of pressure oscillations
- Colliding countercurrent pressure waves

The largest source of data are the test records of NASA WSTF. Some of these have been published in a number of presentations and handbooks [1912, 2198, 2199], but it appears that there is a large amount of unpublished data that should be critically reviewed for their relevance in the design of spacecraft propellant manifolds.

In describing the rapid compression test equipment, it should be mentioned up front that the liquid sample attachment for the Olin Technoproducts drop-weight sensitivity tester is essentially already a bubble rapid compression technique. The sample holder is filled with the liquid sample only halfway, and a bubble (usually an air bubble) is left above the liquid level before inserting the burst disc and carefully torqueing down the lid. The correct torque and use of the correct O-ring will assure that the bubble always has the same size. Failing to apply the correct torque (most often caused by excessive friction in rusted threads) will result in scattered results. Hydrazine cannot be initiated under these conditions (Section 8.5.1) at the limit of hydraulic rupture of the burst disc, whereas isopropyl nitrate is so sensitive that it is often used to calibrate the apparatus.

ICRPG and JANAF (precursor of today's JANNAF) at one time issued a test procedure for adiabatic compression testing with a piston apparatus, but the apparatus was very complex, had too many parts that needed to be machined to close tolerances, and has rarely been used [2192].

Most rapid compression tests were conducted in laboratory settings with single tubes, one tube at a time being filled with hydrazine (see following Section 8.8.1.1). This is not always the case with real-life systems that are filled with hydrazine where rapid compression explosions are feared. These systems may have a multitude of L-bends and T- and cross-shaped-branches leading in different directions and with gradually decreasing diameters. System-level surge flow and rapid compression tests are discussed in Section 8.8.1.2.

#### **8.8.1.1 Single-Tube Rapid (Adiabatic) Compression Tests with Hydrazine**

**Early Model Piston Apparatus.** Hydrazine could not be detonated at the maximum rating ( $144 \text{ kg cm mL}^{-1}$ ) of an adiabatic compression sensitivity apparatus consisting of a gas-driven piston compressing a gas bubble in contact with the liquid propellant [2192]. The energy input was calculated as  $115 \text{ kg cm}$  work applied to a  $0.8\text{-mL}$  air bubble. Nitromethane and alkyl nitrates would detonate at much lower adiabatic

compression stimuli in the same apparatus. It was noted that the pressure rise in the sample chamber was preceded and accompanied by system-induced pressure oscillations. The rate of pressure rise in the first oscillation could be as high as 68 GPa/s ( $10^7$  psi/s). A similar piston apparatus was considered as the standard ASTM test, but it was later rejected.

**U-Tube Apparatus.** An adiabatic compression sensitivity study conducted at Aerojet measured four fuels (hydrazine, MMH, MHF-5, and MHF-7) in contact with 11 metallic materials of construction [2161]. The U-tube apparatus used for these experiments was subsequently adapted for safety investigations by several other research groups. It consisted of a 6.35-mm (0.25-in.)-OD tube bent to the shape of a U 152 mm (6 in.) high and closed on one end by a plug. The propellant sample (3 mL) filled only the lower one tenth of the nitrogen-filled tube. The entire assembly could be lowered by remote control into a temperature-controlled bath prior to the test. The upstream end could be pressurized with nitrogen using a fast-acting valve and a burst disk at a rate of 2064 MPa/s (300000 psi/s). Positive tests were indicated by burst tubes. Propellant-material interaction was apparent in the U-tube adiabatic compression tests. The sensitivity threshold temperature was lower for those metals with catalytic activity (nickel) and known reactivity with hydrazine (aluminum). The metals could be arranged in three hazard groups based on the results. Under adiabatic compression conditions, the threshold temperature limit for explosive decomposition of hydrazine was 377–363 K (217–195 °F) in CRES-321, Hastelloy X, Haynes-25, CRES-316, -347, or -304L (decreasing threshold temperature in this order). In the intermediate group, Inconel X and 17-7PH steel would allow adiabatic reaction at 327 K (130 °F). In aluminum-2014-T6 and 6061-T6, the threshold surprisingly dropped to less than 310 K (100 °F). Neither MMH nor MHF-7 was sensitive to adiabatic compression up to temperatures of 533 K (500 °F). Hydrazine vapor was the most sensitive compound tested; MMH vapor was able to desensitize hydrazine vapor. Whereas hydrazine by itself in CRES-304L would explode on adiabatic compression at temperatures above 366 K (200 °F), the addition of 2.5% MMH raised the threshold temperature to 477 K (400 °F). It was noted that MHF-5 was thermally unstable, and the liquid would sometimes explode during heat-up in a hot bath before the adiabatic compression test could be completed, but MMH contained in MHF-5 stabilized the vapor phase such that vapor-phase adiabatic explosions could not be initiated below 477 K (400 °F). Since the completion of the Aerojet study, there have been fewer investigations on the effect of materials of construction on the threshold of rapid compression deflagrations. It is now assumed that other than through physical properties, such as thermal diffusivity, surface roughness, and yield strength, the wall material has little effect on the rapidly occurring events in the froth zone.

In addition to U-tube tests in which the dead-ended cavity at the end of the tube was at the same temperature as the liquid, Aerojet also conducted several so-called confirmatory tests in which the slug of hydrazine was at 338, 358, or 373 K and it was

pushed into a 7.5-cm-long cavity preheated to 461 to 634 K [2161]. In the case of CRES-304, explosions occurred at 561 and 634 K, but in the case of 17-7PH, explosions occurred at lower temperatures (500, 515, and 555 K). The confirmatory tests were intended to demonstrate that the material of construction is an important factor in adiabatic compression events.

At lower compression ratios and slower compression rates than in the Aerojet tests, no hydrazine detonations were observed in U-tubes [2193–2195]. These tests were conducted to simulate the rapid pressure fluctuations and heat soakback that could be expected for the hydrazine feed system in the Space Shuttle APU. The Hazards Research/Sundstrand test method, also a U-tube adiabatic compression test, was patterned after the Aerojet tests, and the materials tested were those present in the space shuttle fuel system, in particular the fuel pump and the gas generator valve. The Space Shuttle fuel pump was expected to create compression ratios of up to 19:1 and compression rates of approximately 206 MPa/s (30000 psi/s). During previous tests, soakback temperatures of 408 K (275 °F) had been measured in the GGVM valve and near the pump, which might cause a possibly hazardous situation when compressing a hot gas bubble saturated with hydrazine vapor during hot restart.

For the initial Space Shuttle simulation tests, two test conditions were selected, first start and hot restart conditions. The initial start conditions allowed some air in the system. Samples were conditioned at 300 K and were compressed to 3.03 MPa at a rate of 172 MPa/s (25000 psi/s). The gas in the hot restart simulation was nitrogen, the U tube with hydrazine in it was conditioned to 408 K (275 °F), the compression ratio was 20:1, and the compression rate was 345 MPa/s (50000 psi/s). The U tubes were 6.3-mm (0.25-in.) OD, 0.89-mm (0.035-in.)-wall stainless steel. Because not all materials were readily obtained in tube form, some were inserted into the dead-end section of the U tube in the form of sleeves made from approximately 19-mm (0.75-in.)-diameter bar stock into which an axial hole was drilled with a diameter equal to that of the connecting stainless-steel tube. None of the 11 materials tested [CRES-304, CRES-304L, Steel 15-5PH, Steel 17-7PH, Tool Steel M-2(QQ-T-590), Al-2024, Al-355, Greek Ascaloy AMS5616, Ti AMS 4967, Graphitar 86, and tungsten carbide] caused or catalyzed adiabatic compression detonations with anhydrous hydrazine under any of the conditions tested. The apparatus should have been tested with a liquid known to be susceptible to adiabatic compression initiation, such as 2-propyl nitrate or ethyl nitrate, before starting the tests with hydrazine. It is always valuable to have tests with a referee fluid known to be sensitive to make sure that the apparatus works properly and to give other investigators who copied the same apparatus a chance to calibrate their system.

In the continuation of the rapid compression tests for STS APUGG, it was noted that the U tube quite often ruptured upstream of the liquid sample in the U tube, and the reproducibility of the tests was very poor [2196]. This series involved 124 U-tube tests and concentrated on just CRES-304L metal tubes but kept the geometry and test conditions of the first series. Only 1 out of a total of 42 explosions occurred on the downstream side of the sample where one would expect it. As the result of this

observation, the U-tube method was abandoned. One important finding was that helium sensitized hydrazine to rapid compression. Tube rupturing was less likely with nitrogen as the gas in the cavity. This can be explained by the different adiabatic coefficients of the monatomic gas helium ( $\gamma = 1.67$ ) versus a diatomic gas like nitrogen ( $\gamma = 1.40$ ). As a result of these tests, the pressurant gas for STS APU was changed from helium to nitrogen. It is common practice to show the boundary between safe and unsafe in a plot of pressurization rate vs. initial sample temperature. Unfortunately, rarely could enough tests be conducted to exactly pinpoint the location of a fiftieth-percentile curve such as is often done in drop-weight sensitivity tests in a probit plot. When comparing the nitrogen curve demonstrating the go/no go boundary in a compression rate vs. temperature plot to the helium curve, it was noted that the helium curve had the expected L shape near hyperbolic shape, but the nitrogen curve was U-shaped. It was difficult to explain why the system became less sensitive as the temperature was increased from 443 to 457 K (275 to 300 °F). It was suspected that under hot conditions the higher vapor pressure of hydrazine diminished the compression ratio. This U shape of the curve was no longer observed when testing moved to a different apparatus with straight tubes instead of U tubes.

Although the investigators concluded in 1978 that adiabatic compression did not appear to be a problem, occasional feed system explosions have occurred during “bench” testing of APUs on the ground under hot soakback conditions. Such hot restart maneuvers were later avoided during in-flight use of the APUs. As a temporary fix to a problem, an active cooling system had to be installed to lower the soakback temperatures in the injector and valve by squirting water on them from the outside. Concern about inadvertent inclusion of bubbles in the propellant continues for three reasons [2197]:

- (1) Bubbles might be introduced into the liquid side of the diaphragm tank during negligent servicing and refueling.
- (2) The propellant is often saturated with nitrogen at higher pressures, and bubbles are released much like opening a bottle of soda water when the pressure drops during expansion downstream of the pump.
- (3) The slow, ongoing decomposition of hydrazine during storage forms gaseous nitrogen.

**Diaphragm-Straight Tube Apparatus.** NASA WSTF modified the U-tube apparatus by keeping the gas feed system the same but replacing the U-tube test section with a sturdy U tube, which would ordinarily never see hydrazine prior to actuation, on the top of which was placed a flanged test chamber in which 1 mL hydrazine was separated from the pressurant gas by a flexible CRES-304L diaphragm and thin Teflon foil [2197, 2198]. The hydrazine was forced downward into a straight dead-ended 10.5-cm (4.25-in.)-long cavity that could be pre-filled with different gases and could be lined with different metals. A positive event was defined as an event that would rupture the sample tube. There were many experiments where the tube did not rupture, but merely

deformed and bulged. The fail/safe boundary of rapid compressions was mapped as a function of temperature and pressurization rate. In general, this apparatus required pressurization rates several orders of magnitude higher than the U-tube apparatus for tube rupture to occur, but the tests were somewhat more reproducible than with U tubes. Pressurization rates up to 11.7 GPa/s (1700000 psi/s) and temperatures up to 477 K (400 °F) were tested. In trying to identify some inconsistencies suspected of being caused by using hydrazine from different sources with minor variations of contaminants (but still within MIL-SPEC limits), the effect of additives on rapid compression sensitivity was tested. It is interesting to note that small additions of water or aniline (0.1 to 0.5%) sufficed to make hydrazine noticeably less sensitive to rapid compression deflagrations. Early adiabatic compression tests, carried out 20 to 30 years ago, may have been done with hydrazine of dubious purity and should be repeated with high-purity hydrazine.

It was also observed that liquid column movement and dispersal are essential for explosions to occur. If a gas space on top of a stationary hydrazine sample was compressed with the same rate of compression and same pressure ratio as that used to accelerate and explode a slug of hydrazine, no explosions took place. That mode of testing would be like the stagnant liquid sample in a drop-weight tester liquid sample holder consisting of a steel cup, an O-ring, and a burst disc under a plunger with a central bore for venting.

**WSTF Straight-Tube Apparatus.** Very reproducible operation was achieved with a straight-tube setup at WSTF in which neither the liquid nor the push gas had to flow around corners, minimizing turbulence and maintaining cylindrical plug flow as well as possible [2199]. A 10-L Hoke cylinder served as push gas (compressed nitrogen) accumulator. The test results may vary significantly with the type and speed of fast-acting valves used to pressurize the slug of hydrazine with the push gas. Initially, the 10.2-cm/10.2-cm (4-in./4-in.) apparatus used dual metal burst discs to obtain rapid pressurization on the upstream side of the slug of liquid. There was concern that hot metal fragments from the sheared burst discs might initiate reactions, and the burst discs were replaced with fast-acting valves, which allowed faster turnaround between tests and did not add to the cost of consumable items like burst discs that had to be replaced after each test. Later tests used fast-acting gas valves, first a 1-in. Marotta poppet solenoid valve (which did not open very fast in the low-pressure regime but can open within 8 ms at higher pressure), then a pneumatically actuated 12-mm (1/2-in.) Whitey ball valve. The problem with gas valves is that they may leak while the push pressure is adjusted to the desired level and the Teflon foil holding the hydrazine may bulge or rupture prematurely. It is good practice to attach a short-coupled pressure transducer in place of the hydrazine test section and check for gas leakage immediately prior to attaching the test section.

One of the initial setups used multiple 10-cm (4-in.)-long sections of tubing (identical diameters) separated by 2-mil (50  $\mu$ m)-thick Teflon foil to hold the hydrazine in place prior to the test. The 10-cm (4-in.) test sections were like those placed on top

of the earlier flanged diaphragm apparatus. One lower section was the gas cavity; the other served as the hydrazine reservoir. The two sections were flared on both ends and connected via an AN union. Instead of the flanged diaphragm that allowed only limited travel, the Teflon foil held the hydrazine in place with the intent of maintaining plug flow as much as possible, so the hydrazine would act as a ram piston in compressing the trapped gas at the dead-ended cavity. The Teflon foil would rupture and release the hydrazine as soon as the push pressure was applied. The Teflon foil remnants stayed in place and were not swept downstream with the hydrazine. Initial tests were performed with this arrangement with upward or downward travel of hydrazine. Most of the later tests were performed with downward travel only (gravity effects were not considered significant in comparison to the push pressures of several hundred psig).

In one test series with a push pressure of 13.8 MPa (2000 psig) and 0.5-in.-O.D. tubes, a 10-cm (4-in.) slug of hydrazine at 366 K was pushed into **(A)** a 10-cm (4-in.)-long cavity section filled with dry nitrogen, **(B)** a 20-cm (8-in.) section already filled with 4 in. of hydrazine, and **(C)** a 40.6-cm (16-in.) section already containing 30.5 cm (12 in.) of hydrazine. In case **(A)** (Test Nos. 31, 32, and 33), the tube ruptured at the dead head. In case **(B)**, the tube always ruptured at the bottom of the lower hydrazine column, not at the interface between the two impacting slugs of hydrazine where the gas bubble was compressed. This was surprising and is difficult to explain. In case **(C)**, no line ruptures were observed, but the line bulged at the bottom of the lower hydrazine column (like identical tests with water). The predicted burst pressure of 12.6-mm (0.5-in.)-O.D. CRES-304L tubing with a 1.24-mm (0.049-in.) wall was 17.9 MPa (26000 psi). A hydrotested sample ruptured at 100 MPa (15000 psi) [2199].

Experimentation with different lengths of hydrazine slugs and different lengths of gas cavities showed that ruptures occurred most often with a hydrazine slug of 20.3 cm (8 in.) rammed into a gas cavity of 38.1 cm (15 in.). This was then chosen as the standard geometry, and push pressure, cavity gas, cavity pressure, and hydrazine composition were varied to identify the most important variables.

Results obtained at NASA WSTF with the straight-tube apparatus (20.3-cm = 8-in. slug of hydrazine accelerated into a 38.1-cm = 15-in. cavity, hydrazine held by Teflon foil) are summarized in Table 87. These tests were aimed at determining the minimum push pressure that might cause line ruptures, and each hydrazine test was repeated at least three times under identical conditions.

In the NASA WSTF tests summarized in Table 87, none of the identical tests with water instead of hydrazine produced any line ruptures. Several tests were conducted with rapid response pressure transducers in various sections of the cavity, most notably at the dead-end cavity. It appeared that the rapid compression explosive event in the 20-cm hydrazine/38-cm cavity geometry occurs within 40  $\mu$ s from the beginning of the pressurization. Impact velocities of the slug at the dead-head were on the order of 50 m/s with a push pressure of 1.37 MPa (200 psig) and 90 m/s with a push pressure of 3.44 MPa (500 psig). One author of a design guide for hydrazine flight systems

<sup>a</sup> Prevailing atmospheric pressure at test site

suggested that the limiting criterion used to raise a red flag should be the hydrazine impact velocity rather than pressurization rates or compression ratios.

All tests in Table 88 were performed with the cavity filled with nitrogen gas at ambient pressure at WSTF. Since WSTF is located 1520 m (5000 ft) high, the normal atmospheric ambient pressure at that high desert location is only 85.6 kPa (12.4 psia). It appears that already minor fluctuations in cavity pressure, such as that caused by the test site elevation, may affect the outcome of the tests. Other organizations located at lower elevations and attempting to reproduce the WSTF results were not able to do so until the ambient pressure at White Sands was simulated by lowering the cavity pressure prior to each test.

In a test similar to an earlier test (0.5 tube diameter, 366 K, 2000 psia push pressure, 8 in./8 in.), but with water instead of hydrazine, the cavity tube end bulged only slightly from surge flow due to water hammer.

**Effect of Cavity Length on Surge Pressure.** The data summarized in Table 88 contain 8 tests where the cavity length (“bottom section”) was varied while all other variables were kept constant. It appears that the longer liquid slugs encounter flow resistance and eventually reach a constant speed not fast enough to cause hydrazine deflagration or hydrodynamic surge pressures high enough to cause the tubing to yield. With the longest tube, the surge pressures of hydrazine were only slightly higher than those of water and the difference could be explained hydrodynamically by different compressibilities.

**Effect of Flow Restrictions on Rapid Compression.** When a 1.3-mm (0.05-in.) or 2.5-mm (0.1-in.) orifice was inserted between the top and bottom chambers and tests repeated at room temperature, no line ruptures occurred in any of the tubes under conditions where the tubes would have ruptured without orifices. Most monopropellant hydrazine flight systems have orifices in the manifold, either in the form of enable and latch valves, cavitating venturi, or trim orifices to match pairs of thrusters. Rapid compression damage by hydrazine explosion is much less likely in the presence of ori-

fices, and this may explain why damage in hydrazine flight systems so far was limited to pressure surges that could be explained by hydrodynamics alone.

**Effect of Contamination by Residual Water on Rapid Compression.** When a trace of water was inadvertently left in the cavity, the tubes would not rupture under conditions where dry tubes would have ruptured. Adding 30% of water to the hydrazine (such as in the H-70 fuel blend) essentially suppressed all rapid compression sensitivity even under the most severe conditions tested at WSTF.

In a graph (Figure 66) where the surge pressure for water, hydrazine, and hydrazine/water blends is plotted versus the surge pressure observed for water in the same apparatus, the water data are represented by a straight line.

Tests with hydrazine, 90% hydrazine, and 80% hydrazine showed that for surge pressures below 17 MPa (2500 psi), the three curves stay close together and agree with data for hydrodynamic surge. At surge pressures above 17 MPa, the monopropellant-grade hydrazine showed a large deviation and surge pressures above 34 MPa ruptured the tubes. The deviation for 80 and 90% hydrazine became apparent only at surge pressures above 24 MPa. These deviations are the result of chemical reactions and not simply a hydrodynamic effect caused by different compressibility.

**Figure 66:** Resulting pressures and calculated adiabatic temperatures at various peak hydrodynamic pressures. (Reproduced and modified from [2201], with permission from ©1991 American Institute of Aeronautics and Astronautics 7-Jul-2021.)

**Effect of Increasing Top Chamber Diameter.** Although most of the WSTF tests were conducted with top and bottom chambers of identical diameters, a few tests were conducted with a wider top hydrazine reservoir (2.54 cm = 1 in. OD) than the bottom cavity (1.27 cm = 0.5 in. OD). Both top and bottom chambers were 10 cm (4 in.) in length. Both tests with push pressures of 3.5 MPa (500 psig) and 6.9 MPa (1000 psig) resulted in ruptures not only of both lower and upper chambers, but also rupture of the 19-mm (0.75-in.) line carrying the pressurant gas, overall major destruction.

**Conditions in Liquid Front Rushing into Cavity.** It appears that conditions in the slug of liquid, in particular at the front of the liquid column, as it is rushing into the gas cavity will determine whether or not an explosion will take place. For very short

slugs ( $<10$  cm), gas pressure may break through as core flow and squeeze the liquid on the wall, leaving it behind, not leading to an explosive event. If the slug is too long, flow resistance will increase with the length of the liquid column and the slug will slow down before it bottoms out. An intermediate length of liquid columns is susceptible to rapid compression. Tests with an inert X-ray opaque contrast fluid and X-ray photography during the test were not very helpful. A series of high-speed film frames was obtained with a see-through glass tube instead of a stainless-steel tube, showing a froth of an intimate mixture of liquid and gas bubbles [2199, 2201]. The high-speed photography was very informative as to the nature of the liquid front entering the gas cavity. Discussions centered around the source of the bubbles, if they were released as dissolved gas from the hydrazine or if they were entrained bubbles. The initiation mechanism of the explosive hydrazine decomposition was shown to be dependent on the formation of a froth with subsequent rapid temperature and pressure increase by ram effects. The general interpretation was that the froth is formed by entrained bubbles. Taylor instabilities at the liquid-gas interface and Helmholtz mixing result in an intimate mixture of hydrazine, hydrazine vapor, and gas bubbles in the rapidly moving mixture of the three. Based on the tests at NASA WSTF, it is now concluded that the rapid compression of hydrazine froth does not initiate a detonation (as was the case with nitromethane under similar test conditions [2192]), but the heat from the compressed bubbles is rapidly transferred to thin membranes of liquid hydrazine, creating a thermal runaway situation, which is as destructive as an explosion.

**Effect of Temperature on Rapid Compression Sensitivity.** The importance of the initial system temperature on the susceptibility of hydrazine to rapid compression became painfully apparent during the Space Shuttle APU hot restart tests. It was obvious that raising the initial temperature of the hydrazine would reduce the additional energy required to bring hydrazine/gas bubble mixtures to the threshold of explosion. For satellite manifold applications it is generally assumed that propellant and system are at the same temperature. There do not seem to be any tests where the propellant reservoir and the cavity were temperature conditioned at different temperatures.

**Effect of Cavity Pressure on Rapid Compression Sensitivity.** A series of tests was performed at WSTF in which a 20-cm (8-in.) column of hydrazine or water was accelerated into a 38-cm (15-in.) cavity chamber filled with nitrogen at pressures ranging from near vacuum to 141 kPa (20.4 psia) [2199]. The results are summarized in Table 89 and illustrated in Figure 67.

It is significant to note that based on the WSTF tests, there is only a narrow range of cavity pressures within which rapid compression explosions were observed for these particular geometric and operating push pressure conditions. At the high-pressure end, it is easy to explain that the gas in the cavity acts as a spring and shock absorber, slowing down the incoming slug of liquid (which will eventually rebound). This concept of a high pad pressure was used with advantage by several flight systems (e.g., IUS) to protect against unwanted rapid compression/water hammer events

**Table 89:** Effects of gas cavity pressure on surge pressure and hydrazine decomposition.

when a manifold is first filled with hydrazine. It is more difficult to explain why no explosions occur with vacuum and at very low pressures, although the compression ratio is significantly higher. It is assumed that at the low-pressure end of the pressure regime there is not enough gas to entrain and form hot spots. Surge pressures for water and hydrazine were similar at the lowest cavity pressure tested [2199].

**Effect of Type of Cavity Gas on Rapid Compression Sensitivity.** One of the first significant findings of the WSTF tests, confirmed by testing in different apparatus and test tube geometries, was that helium rendered hydrazine more sensitive to adiabatic compression than nitrogen. Subsequently, hydrazine pre-pressurization on the Space Shuttle APU was changed from helium to nitrogen, although the Space Shuttle APU used a diaphragm tank and hydrazine was not in direct contact with the pressurant gas. Enough pressurant gas may permeate through the diaphragm during year-long storage and form trapped bubbles in the hydrazine. Hydrazine in the Space Shuttle APU tanks was only primed to a feed pressure of 2752 kPa (400 psia), and this was subsequently boosted in a gear pump for actual APU operation at 9.63 MPa (1400 psia). Bubbles were compressed as they passed through the pump and during pulse-mode operation of the control valve.

The sensitivity of pressurant-gas-saturated hydrazine depends on the type of gas contained in the cavity and in the bubbles. The difference in sensitivity to rapid (“adiabatic”) compression explosions can be explained by the difference in the adiabatic coefficient  $\gamma = C_p/C_v$  of nitrogen (a diatomic gas) and helium (a monatomic gas). The gamma of nitrogen is  $\gamma = 1.4$ , whereas for helium it is  $\gamma = 1.66$ , resulting in higher adiabatic compression temperatures in accordance with

$$T_2 = T_1 \left( \frac{p_2}{p_1} \right)^{\left( \frac{\gamma-1}{\gamma} \right)}$$

All nominal tests were conducted with nitrogen as the push gas and nitrogen in the cavity. In a rare test with helium as the push gas and nitrogen in the cavity, a 0.25-in.-O.D. tube ruptured with a push pressure of only 2.06 MPa (300 psig) instead of 3.44 MPa (500 psig) as with nitrogen push gas. This indicates that helium is more effective as push gas than nitrogen (which is why it is used in light gas guns).

Although the straight-tube test arrangement yielded a large amount of useful data, one question has never been completely answered: What effect do the hydrazine vapors diffused through the Teflon foil have on the results observed in the WSTF straight-tube tests? Since the cavities are hermetically sealed and not purged while the tube is waiting to be tested, hydrazine may diffuse through the thin foil and evaporate into the cavity fill gas. Although the tubes are usually tested immediately after the hydrazine is loaded, there is usually a delay of up to several hours while the test setup is tightened, leak tested, and the instrumentation hooked up. Some tests take several hours to reach the desired test temperature. Tests have shown that the breakthrough time for hydrazine through the same type of Teflon foil as was used at WSTF is less than 1 h and the rate of permeation is  $2.5 \times 10^{-7} \text{ g cm}^{-2} \text{ h}^{-1}$ .

NASA WSTF performed an additional series of rapid compression tests, initially with water and instrumented with numerous pressure transducers [2202, 2203], then with live hydrazine in support of the RCS/ACS system intended for the Space Station Freedom. In these tests, all hydrazine was contained in a larger reservoir, such that longer manifold sections (all 12.5-mm [0.5-in.] O.D.) with branch passages could be entirely filled with liquid. The problem with hydrazine permeation through the Teflon foil was avoided since the Teflon foil was replaced with a Carlton Controls poppet valve, capable of opening full bore within 10–20 ms. Feed pressure was nominally 2.75 MPa (400 psig), and none of the test sections with hydrazine ruptured under those feed pressure conditions. For much higher feed pressures and a 38-cm (15-in.) straight section, as used in earlier tests, feed pressures of 17.2 MPa (2500 psig) may result in the rupture of nitrogen-filled cavities, but only 10.3 MPa (1500 psig) may rupture cavities filled with helium or argon.

The French space agency also sponsored research on the study of the decomposition of hydrazine by rapid compression and its application to explosion hazard evaluation [1192, 1257, 2204].

#### **8.8.1.2 Rapid Compression Hazards in Flight System Manifolds**

There was concern that the sudden compression of hydrazine rushing into an evacuated propellant manifold on actuation of tank isolation valves in the IUS might cause explosions resulting from adiabatic compression and decomposition of hydrazine [2205]. Another damage mechanism would be pressure surges by the water hammer effect, which is a strictly physical phenomenon involving no chemistry but is aggravated by the low compressibility of hydrazine in comparison to that of water. In evacuated manifolds, hydrazine pressure surges of up to 49 MPa (7200 psi) with 0.4-ms duration were measured. Several methods were evaluated to suppress the surge, and pre-pressurization of the manifold with nitrogen was shown to dampen the water hammer effect. Similar pre-pressurization studies were conducted for other flight systems. It is difficult to ensure that the gas pad stays there until propellant is dropped into the manifold. Launch vibrations may unseat the thruster valves and allow some of the gas to leak out. Launch delays may require re-pressurization of the manifold prior to the next launch attempt.

The large pressure transients observed when hydrazine is released into an evacuated dead-ended tube are related to the low elastic compressibility (i.e., high velocity of sound) of hydrazine. This effect is more pronounced with hydrazine than with water because the velocity of sound in hydrazine is 1.4 times faster than in water.

**ISPM (Later ULYSSES) Manifold Filling Test.** The ISPM filling test was conducted at ERNO (later a division of MBB/DASA) in cooperation with British Aerospace to simulate the unlikely situation that the IUS/PAM-S-assisted launch from a Space Shuttle in orbit had to be abandoned and the spacecraft had to be brought back to Earth [2206]. The radioisotope thermal generator would have heated the entire space probe from the time the Space Shuttle payload bay doors were closed and the bump

on touchdown on the runway might have been severe enough to flip the latch valves open. The test series summarized in Table 90 was conducted to assess different “what if?” hazard conditions.

**Table 90:** ISPM manifold filling tests

| Test No. | Tubing temperature, K | Feed pressure, bar | Cavity pressure, bar | Hydrazine temperature, K | Filling condition                                       |

Data source: [2206]

One of the options considered to minimize the pressure spike when first dropping pressurized propellant into the lines downstream of the latch valve was to pre-fill the lines partially with hydrazine and nitrogen at sea-level pressure. This option includes the risk that some of the unpressurized propellant will leak through the TCVs into the catalyst bed while the spacecraft is still in the Space Shuttle payload bay. Test Nos. 6 and 7 with hydrazine vapor in a dry line simulated a leaking latch valve. The line diameter for the tests was not given, but it was assumed it was close to 6 mm (1/4 in.). A manifold representing half of the symmetrical satellite propellant feed system was pre-heated to nominal 351 K = 78 °C = 172 °F. When hydrazine pre-heated to 363 K = 90 °C = 194 °F and pressurized at 30 bar (435 psia) was allowed to enter the manifold (filled with saturated hydrazine vapor at the vapor pressure at 351 K = 78 °C = 172 °F which is 42 kPa = 6 psia) through a latch valve, an explosion ensued after 361 ms which destroyed the line system and the filter. The last temperature recorded inside the manifold was 440 K = 167 °C = 333 °F due to the adiabatic compression of the bubble. The fragments of the remaining hardware gave the impression that explosions occurred in several places simultaneously. Post-event examination of the experimental setup concluded that the line sections had been inadvertently overheated locally to substantially above the nominal test temperature by crisscrossing and double-layering the heating tape in some areas, creating hot spots. The test was later repeated with a hot water bath at temperatures up to 363 K, providing more uniform temperature control, and no explosion was observed during the repeat test. For a while some critical voices out there in the propulsion community suggested that the water bath surrounding the tubing attenuated the shock wave propagating through the metal wall of the tubing and prevented the hydrazine from exploding as before. If the phenomenon is inter-

puted as an LVD, surrounding water might indeed attenuate the shock wave advancing through the stainless-steel tubing. Also, the ability of the cavity to expand and contract in multiple oscillations would be impeded by surrounding water. The pre-test temperatures in ground test inadvertent explosion events assumed to be due to hydrazine rapid compression were substantially above typical satellite manifold temperatures. The high temperature in each case sensitized the system to rapid compression explosions. On the other hand, line diameters were below the 9.5- and 12.2-mm (3/8- and 1/2-in.) O.D. lines now flown on many larger satellites. In many flight systems, a pad pressure ("gas cushion") is placed in the manifold before dropping hydrazine into it for the first time. One of the first systems to use this technique was IUS, and this practice was later adopted by many other systems (PAM-D, DELTA-II, ATLAS-II Roll Control Module). The preferred padding gas is nitrogen, but for unknown reasons, some satellite designers still prefer helium, although it may make rapid compression hazards worse (if only part of the gas cushion leaks out during launch vibrations) and it leaks out faster than any other gas. It is very likely that some of the pad gas leaks out during launch vibrations when the thrust chamber valve poppets start jumping up and down on the seats. It seems that nobody has proven that the pad gas is still there when the propellant is dropped into the manifold. It has been suggested that the propellant should be dropped as early as possible during the launch sequence.

Most Defense Support Program (DSP) satellites, except DSP-16, were launched on expendable launch vehicles and the manifold lines were filled with hydrazine prior to launch. STS payloads, on the other hand, require at least three inhibits to prevent leakage of propellants in the payload bay. To meet this requirement, DSP-16 was launched on STS-44 with dry manifold lines. Prior to launch, the potential for rapid compression-induced decomposition and detonation was investigated through analysis and test [2207]. Testing involved accelerating hydrazine into simulated line ullages for several ullage pressure conditions and dead-head cavity temperatures. These efforts demonstrated that the DSP plumbing system and fill procedure were not susceptible to adiabatic compression hazards of hydrazine. Operationally, a technique to manage a gas pad before and after propellant line priming was developed, and on-orbit activation of the propulsion subsystem went smoothly as expected.

Propellant manifolds on SPOT 4 satellites and precursors were usually filled with hydrazine prior to launch and a small (~1 mL) gas bubble was deliberately formed at the thruster end of the lines to allow for thermal expansion of the liquid. When scaling up the SPOT design for the Polar Platform Propulsion System (ENVISAT), a different approach was necessary because the lines were up to 13m long and the gas bubble would have been too big, and its location was unpredictable. Matra Marconi Space performed a very thorough mathematical analysis of propellant velocities during gas cushion discharge through the thrusters [1926]. Some of the equations derived there are also applicable to predicting rapid compression events caused by moving slugs of liquid. Since the pressure drop during gas cushion discharge through the thruster was low, propellant would be able to accelerate to high speeds, causing severe water ham-

mer spikes when the thruster valve was suddenly closed. Loading strategy alternatives of complete liquid fill or gas-only fill were not acceptable. The best solution was to introduce small bubbles of known size into each leg of the system by slowly filling it with propellant that was pre-saturated with helium at 3.53 MPa (35 bar). When this propellant expanded to sea-level pressure during filling of the manifold, a known amount of gas was released and would rise to the top of the vertical lines leading to the thrusters.

Hydrazine is not the only rocket propellant where explosions can be caused by rapid compression of propellant lines. Oxygen rushing into empty lines has been known to cause ignition of combustible materials, even inert polymers like PTFE. The mathematics, thermodynamics, and fluid dynamics of oxygen compression “adiabatic” heating in dead-ended tubes can be applied to the hazard prediction in hydrazine systems as well [2208].

### **8.8.2 Water (Fluid) Hammer and Surge Flow Conditions Conducive to Rapid Compression Events in Hydrazine**

As already discussed in earlier sections, water (fluid) hammer and surge flow with any liquid (reactive or not) can result in destructive pressure spikes. This is particularly true with hydrazine due to its low compressibility (compared to that of water). We list here some examples where such pressure spikes have caused hardware damage, but (as far as can be discerned from the information available) without participation of hydrazine decomposition reactions. Various observers have suspected that the rapid compression of hydrazine might have been the culprit for these events, but this has not been proven, and the explanation of a strictly physical, not chemical, phenomenon has generally been accepted. In what follows, the effects of surge flow (“priming”) into evacuated or low-pressure propellant manifolds are discussed first, and the effects of water (fluid) hammer, usually observed in completely filled lines, are discussed second. Some computer models may be capable to handle both types of compressible fluid flow. Not all models can handle multi-phase fluid flow. Experiments in replicas of actual flight plumbing systems are often conducted with water instead of hydrazine, and the results were extrapolated to hydrazine by adjusting for a different compressibility. But those extrapolation methods neglect the potential reactivity of hydrazine in two-phase flow situations.

#### **8.8.2.1 Surge Flow Conditions Conducive to Rapid Compression Events in Hydrazine**

Most satellite propulsion systems are activated in orbit by rapid opening of a pyro valve, dropping propellant into evacuated or partially gas-filled propellant lines. This is typically done after the last stage of the launch vehicle has completed its burn phase and the satellite has been injected into a low Earth orbit or a geostationary transfer orbit. The dropping of the hydrazine monopropellant into the manifold is delayed because launch vibrations might unseat some of the solenoid valves and allow propellant to leak if this downstream point of the system was wet and pressurized. This

process is also called “priming” or “dropping propellant.” The following discussion of hydrodynamics applies to all liquids and all propellants, but the conditions are most severe for hydrazine because of its small compressibility. If priming and water hammer problems occur with any rocket propellant, they will occur with hydrazine first. The severity of pressure spikes by surge flow into evacuated or low-pressure gas-filled lines could be limited if slow opening pyro valves were available. Unfortunately, most pyro valves available at this time open within milliseconds and send a surge of propellant into the manifold that needs to be filled with propellant. In all cases the solenoid valves at the end of these runs of line are closed at the moment the propellant is dropped into the manifold by firing the isolation valve or opening a latching valve. Many system designers specified a gas pad that will cushion the impact of the slug of liquid. However, the first series of pulses commanded to the thrusters will then be unpredictable until all the bubbles have been passed through the thrusters. Some trapped bubbles may linger around in filters and soften the hydraulics of the system and may move around unexpectedly at another time. Another method to slow the rapid advance of the propellant is to insert flow restrictors (orifices, cavitating venturi) upstream or downstream of the pyro valves. Most of the papers referenced here are valid for any fluid, not just hydrazine. The equations apply even to plain water, which is often used as a surrogate for hydrazine when testing new propellant distribution manifold designs. It is only the close relationship between surge flow pressure spikes and rapid compression explosions of hydrazine that is the justification for assembling all these papers and discussing them next to each other in the following section. Not all computer models described here are able to account for the release of dissolved gases while the column of liquid advances through the low-pressure section of the plumbing system. None can predict accurately when hydrazine will explode. Some of the models ignore the fact that the explosion may be triggered, not at the first impact pressure spike, but only after the first rebound and a reflected rarefaction wave that creates additional cavitation bubbles for the subsequent compression cycle as the system oscillates and gradually rings out. Additional bubbles create the two-phase medium that can propagate an LVD-like deflagration in hydrazine.

In January 1976, the Canadian CTS satellite experienced an anomaly when a latch valve was opened to fill an evacuated line [1826]. The latching valve vibrated (“fluttered”) and the downstream line did not fill completely within the allocated 3-s fill time. Critics suspected this could have been a rapid compression/adiabatic compression explosion event, but this was never proven.

A simplified model was derived to describe the flow of MMH (and NTO) into evacuated and pressurized straight lines, which allows for the prediction of peak pressures [2209]. This is described in the chapter on methylhydrazine. The model can be modified to be applied to hydrazine.

In the case of Compton Gamma Ray Observatory (CGRO), the concern about surge flow and water hammer damage to thruster valves was so dominant that it was considered to fly the propellant lines filled with hydrazine prior to launch

on the Space Shuttle. The propulsion subsystem had two independent branches called A-Side and B-Side. In April 1991, the GRO hydrazine propulsion system was accidentally subjected to high surge pressures during the on-orbit pressurization of the primary propellant manifold. Immediately upon opening one of the propellant tank isolation valves, the spacecraft telemetry indicated that two isolation latching valves had undergone uncommanded changes in the open/close position status (“flip-flopped”) and one of the pressure transducers indicated “over limit” pressure. A TRW analytical pressure transient model, which was correlated with test data as part of the CGRO surge pressure anomaly investigation, supported the following proposed mechanism for the high surge pressure: A relatively large volume of bubbles was inadvertently trapped in the thruster manifold downstream of the tank isolation valves. It had been introduced with supersaturated propellant during loading of the spacecraft on the ground. A sufficiently large pressure differential existed at the tank isolation valves (2.62 MPa = 380 psia propellant tank pressure; 0.101 MPa = 14.7 psia in the manifolds downstream of the tank isolation valves). A high surge pressure was initiated by the opening of the tank isolation valve and leaving it open instead of pulsing it. A NASA investigation determined that an oversight in a fuel loading procedure had left a significant volume of bubbles in the propellant lines [2210–2214]. A method to command the tank isolation valves in “pulse mode” (“fast cycling”) was successfully developed, characterized by testing, and applied to the CGRO redundant B-Side manifold when it was activated. In April–July 1993, this pulse-mode method was used to seep propellant from the propellant supply into the redundant B-Side thruster manifolds to gradually raise the downstream pressure prior to fully opening the valves for an orbit adjust maneuver. The priming of the B-Side Attitude Control Thrusters (ACTs) manifold required approximately 3500 cycles of the isolation valves. The priming of the B-Side Orbit Adjust Thrusters manifold required an additional 400 cycles. It was concluded that slow opening isolation valves need to be developed.

Several small satellite feed systems were tested on the ground for their surge flow and water hammer characteristics. Pressure drops across filters and latch valves were measured using water as a simulant fluid [2215].

The SeaStar Hydrazine Propulsion System was a blowdown monopropellant system used for orbit raising and maintenance and consisted of a single propellant tank with an expulsion diaphragm, a pyrotechnic isolation valve, four thrusters, two pressure transducers, and three service valves. Initial analysis of the system configuration indicated a potential failure mode due to adiabatic detonation of the propellant during system activation. To further understand the potential of high-pressure surges as a consequence of water hammer effects during activation, a test was performed with water as the surrogate fluid [2216].

In a more complex system, the surge flow of hydrazine into the evacuated or gas-filled propellant manifold of the hydrazine monopropellant propulsion subsystem of the planned Space Station Freedom was simulated with water flow tests and the pressure spike results were compared to predictions from a method-of-characteristics com-

puter model [2202, 2203]. Tests were conducted with straight-line sections, elbows, branch passages, and junctions. The feed pressure was 2750 kPa (400 psia) and the line diameter was 12.7 mm (0.5 in.), which is a wider diameter than typical satellite lines. The test results showed an increase of surge pressure with straight-line length from 25 to 50 and 75 cm. The pressure-time curve of the priming process could be closely matched with computer predictions. The experimental results were in between the theoretical predictions for an adiabatic and isothermal compression process.

Pressure transients during priming of a spacecraft propulsion subsystem have the potential to significantly affect on-orbit performance or can result in a catastrophic loss of spacecraft. A series of tests were performed to quantify the expected pressure transients experienced within a spacecraft propulsion system fuel manifold during on-orbit activation [2217]. Results have then been analytically correlated based on line travel distances and compared to recorded pressure values in order to establish a tool for predicting pressure surges at conditions outside the test envelope. Testing was designed to emulate priming of the propulsion system by pressurizing water to approximately 1.03 MPa (150 psia) and releasing it through the actuation of a solenoid valve into an evacuated tubing manifold representative of the Star-2 propulsion system. At this pressure, the fluid velocity attained was enough to generate a pressure surge once the flow was stopped suddenly by encountering a closed thruster valve in the system. Assumed design limitations were as follows: **(1)** a pressure spike in hydrazine fluid absolutely should not exceed 17.2 MPa (2500 psia) due to the risk of adiabatic compression explosion; and **(2)** component proof pressures should not be exceeded. Of the 26 test runs performed with and without water-hammer-suppression orifices, none resulted in surges exceeding or approximating the hazardous adiabatic compression explosion regime. Without suppression orifices, pressures as high as 13.4 MPa (1938 psia) were observed (correlated for hydrazine conditions) at the dead end having the greatest distance from the fluid release point. The installation of water-hammer-suppression orifices safely reduced the pressure surge values to non-hazardous levels of no more than 3.7 MPa (540 psia).

A computational method for analytical prediction of priming surge flow water hammer pressure has been developed and applied to the design and development of several spacecraft propulsion systems [2218]. The approach involved deriving and solving equations of motion for the fluid as it surges into a downstream manifold and impacts locations in the feed system. The technique has been validated using results of testing where actual measurements of water hammer were obtained. It offers improved accuracy over simpler calculation techniques and can provide sufficient accuracy in many cases without resorting to complex fluid codes. Results of these analyses have been used to confirm component and subsystem acceptability, determine the need for surge suppression, and guide the planning of verification experimental testing.

An experimental study was carried out with real propellants, such as hydrazine, MMH, and NTO, in comparison to water, and fluid hammer was measured into straight

pipe, bent pipe, elbow pipe, and tee pipe [2219]. Measurements have allowed us to obtain overpressure levels, to determine the sound velocity in the liquid propellant, and to define the speed of the flow by the transition time gas/liquid.

An experimental investigation of the water hammer phenomenon in a confined environment was carried out using a simplified setup with two inert fluids, ethanol and acetaldehyde, and an actual propellant, MMH [2220]. Numerous tests confirmed the excellent reproducibility of the results. The experiments showed that ethanol could be used as a surrogate fluid instead of toxic MMH for the water hammer amplitude measurements. The water hammer phenomenon produced in a pipe with a low initial pressure exhibited a complex evolution over time and slight differences in amplitude and features depending on the pipe geometry.

The classical surge flow water hammer taking place during priming involves multi-phase phenomena, such as cavitation and absorption/desorption of a non-condensable gas, which affects the pressure spikes produced in the lines. Even though this flow behavior is known, only a few studies model specific spacecraft hardware configurations, and a proper characterization of the two-phase flow is still missing. An experimental facility modeling a spacecraft propulsion system was built, where the physical phenomena taking place during priming can be reproduced and measured [2221–2223]. The influence of the driving pressure gas dissolved in the propellant was analyzed using either a saturated or a completely de-aerated test liquid. Two-phase flow was characterized by means of flow visualizations of the liquid front at the location where the fluid hammer is generated. For this purpose, an experimental study was carried out with inert fluids modeling a liquid propulsion system, where the gas saturation level of the test liquid was controlled, making it possible to run experiments under de-aerated and saturated conditions [2224, 2225]. An experimental investigation on the fluid hammer phenomenon taking place when filling a pipeline under vacuum conditions with a closed end was carried out in a facility allowing flow visualization, which was made possible by replacing the metal pipe closed end by a quartz cylinder drilled with the same tube inner diameter [2226]. In this way, the flow can be recorded with high-speed imaging at this location. The visualizations confirmed that the pressure evolution is accompanied by a complex multi-phase flow pattern. First of all, a foamy mixture of non-condensable gas, vapor, and liquid droplets precedes the liquid front arrival at the bottom end. During the fluid hammer compression wave, the vapor condensates and the non-condensable gas gets compressed. Afterwards, the arrival of an expansion wave induces the movement of the liquid column backwards, with the corresponding pressure drop that generates a gaseous bubble referred to as column separation. Finally, the collapse of this bubble is at the origin of the next pressure rise. A sequence of images showed a foamy mixture preceding the liquid front and the non-condensable gas compression when the front first impacts at the bottom end, the subsequent column separation with the creation of a multi-phase bubble, ending with a new impact of the separated liquid column against the bottom end. A higher release of desorbed

pressurant gas in the lines cushions the liquid front impact at the closed ends, inducing a lower pressure spike during fluid hammer occurrence. Ethanol or water were used as surrogate fluids for tests in a vertical tubing with downward flow [2227].

The commercial code CFD-ACE+ was used with a so-called full cavitation model, which considers the effect of absorption and desorption of a non-condensable gas, to clarify some issues of surge flow water hammer [2228]. A comparison between two different compressibility models made use of an inverse engineering technique, which allowed the tracking of the medium velocity of sound. A numerical reproduction of a valve opening leading to a sudden acceleration of the fluid and consequent vaporization of the liquid confirmed high sensitivity of the water hammer pressure spike depending on the amount of non-condensable gas present in the liquid.

From a physical point of view, the modeling of priming is a complex task because it involves transient multi-phase flow. As a first approach, an analytical model of the equations of motion was developed applying a rigid liquid column theory, considering only the inertial and frictional effects of the liquid treated as a slug [2229]. The friction plays an important role, in particular due to the unsteady conditions which increase its steady value. The cushion effect of an inert gas was also analyzed and the assumption of adiabatic vs. isothermal compression compared. Results indicated that a polytropic compression can better model the realistic gas behavior.

There has been a controversy in connection with establishing where the threshold for hydrazine detonability is, due to the high number of parameters affecting the results, the variability of the test conditions (e.g., test setups, initial conditions). An attempt was made to define the conditions where this phenomenon is triggered and a logic and methodology was proposed to resolve this problem [2230].

A network flow simulation software based on a finite volume method was used to predict pressure surges resulting from the sudden opening of a valve in a pipe that has entrapped air at one end of the pipe [2231]. The mathematical model was built by combining the flow equations in the liquid (water) zone and compressibility of the entrapped air. The numerical results were compared with experimental data available in the literature. The study was conducted for a range of reservoir feed pressures and for different amounts of initial air present in the pipe. The numerical results compared well (within reasonable accuracy, less than 8%) for a range of inlet-to-initial pressure ratios when the amount of air present was relatively high ( $\alpha \approx 0.45$ ). A fast Fourier transform was performed on the pressure oscillations to predict the various modal frequencies of the pressure wave.

The Global Precipitation Measurement satellite propulsion system was a blowdown monopropellant system with an initial hydrazine load of 545 kg in a composite-overwrapped propellant tank. At launch, the propulsion system contained hydrazine in the tank and manifold tubes upstream of the latch valves, with low-pressure helium in the manifold tube downstream of the latch valves. The system had a relatively high beginning-of-life feed pressure and long downstream manifold lines. These factors created conditions that were conducive to high surge

pressures, requiring surge mitigation in the propulsion system design and surge testing for verification [2232]. Based on the results of surge testing and pressure drop analyses, a configuration of cavitating venturis was chosen to mitigate surge while minimizing pressure losses during thruster maneuvers.

A study of fluid hammer and related multi-phase phenomena taking place in a confined environment, where pressurized liquid faces vacuum conditions after opening an isolation valve, described the experimental facility built for this purpose, the tests performed, and showed a comparison of laboratory test results with the numerical results obtained with a transient one-dimensional software based upon conservation equations [2233]. The leading edge of the liquid rushing into the low-pressure cavity was subdivided into several zones: boiling liquid front, foam (froth) front, vapor front, and gas pressure wave front. The results of the computations were presented in the form of two-dimensional color maps for each of the variables involved (e.g., pressure, temperature), where the history in time  $t$  and  $x$  coordinate along the different nodes can be followed. The  $x$ - $t$  diagrams allowed a simultaneous study in time and space for each of the magnitudes involved in the evolution of the fluid hammer. The tests showed the typical water hammer evolution as a succession of pressure peaks with decreasing amplitude. The multi-phase effect on the velocity of sound needs to be studied more in detail during experiments.

Experimental measurements in an instrumented test section simulating a satellite manifold, with water as the push fluid, were compared with predictions from calculations with the Flownex computer program [2234]. Flownex has the ability to solve the steady-state and dynamic flow simulations of systems in any combination of liquid systems, gas systems, mixtures of gases, two-phase systems with phase changes, and incondensable mixtures of two-phase fluids with gases coming out of the solution.

The phenomenon of priming involves complex two-phase flow: the liquid entering the evacuated pipe undergoes flash evaporation, creating a vapor cushion in front of the liquid that mixes with the residual inert gas, usually helium. Moreover, the dissolved pressurizing gas in the liquid will desorb making the priming process difficult to model numerically. For these reasons, priming and/or water hammer tests are always part of the qualification process of new propulsion subsystems of a satellite or spacecraft that uses storable propellants. Dissolved gases influence a step-plateau pressure trace shape observed in priming tests. To gain further insight into this aspect, a quartz pipe was installed at the dead end of a manifold, and high-speed imaging at framing rates up to 19200 frames/s was performed [2235]. The test section was 220 cm long, and the transparent clear quartz section was 20 cm long with an ID of 16 mm. The image analysis proved to give valuable information to better understand this complex transient phenomenon and a possible explanation of the first pressure peak profile was given based on these visual observations.

An overview of surge flow experiments and computational models for the study of multi-phase fluid-hammer effects in aerospace applications performed by a number of different organizations was given in [2236]. The accurate prediction of the peak pres-

sure transients that occur during the priming of a spacecraft propulsion system is vitally important because these transients can cause damage to components or even trigger the deflagration of hydrazine. Methods are needed for the accurate prediction of the pressure transients in a pipe due to the reflected pressure wave. During the priming of a spacecraft propulsion system, pressure transients occur from the rapid deceleration of propellant from a pressurized manifold to an evacuated manifold downstream of an isolation valve. When the isolation valve is opened, propellant will initially flow essentially unrestrained until the fluid column impacts an obstacle, such as a surge suppression device. In the case of a straight-edged orifice, this will cause cavitation that will slow down the fluid column. The propellant will continue to flow through the downstream piping until it hits a dead end. The initial impact of the fluid column with the dead end will cause a pressure spike. This transient is often referred to as a slug hammer. Once the line becomes filled with liquid, another pressure transient will occur that will cause a pressure wave to travel upstream through all wetted lines and eventually attenuate. This transient is often referred to as the reflected pressure wave. Surge suppression devices have the greatest effect on reducing the pressure spikes due to a slug hammer. Therefore, it is important to accurately predict the pressure transient due to the reflected pressure wave because this transient cannot be mitigated as effectively by simply adding additional margin. AFT Impulse, a surge/water hammer modeling software, was shown to accurately predict the peak pressure transient due to the reflected pressure wave despite some of its modeling limitations, as long as the peak pressure transient is due to the reflected pressure wave [2237].

An experimental research program was conducted to evaluate pressure transient levels in unrestricted liquid monopropellant propulsion system configurations and propellant manifolds generated by surge flow water hammer effects resulting from a priming event [2238]. In a water hammer experimental setup using distilled water as a propellant simulant for hydrazine, multiple test elements were evaluated using different internal diameters, line lengths, and flow control valves, at both atmospheric and sub-atmospheric pressure levels. Based upon experimental results, it was determined that the internal diameter, line length, valve flow coefficient, and valve opening response time all contributed to the pressure spike magnitude of the priming event. It was observed that water hammer pressure levels may be minimized and equally distributed throughout a propulsion system manifold using a ring layout, independent of line geometry, valve flow coefficient, and valve opening response time.

A replica of the manifold of the ExoMars lander retro-propulsion sub-system was built and various fill sequences were tested in the mockup, first with water and then with real hydrazine to prevent the re-occurrence of events such as those that doomed LANDSAT F and TELSTAR 402. A bypass line with an orifice flow restrictor was opened first to fill the manifold slowly before opening the main pyro valves [2239–2241].

The process of filling the downstream feedline can cause severe pressure spikes that could lead to structural failure or even to hydrazine adiabatic compression de-

flagration. For safety reasons the feedline is usually evacuated prior to launch. This causes the propellant to undergo flash boiling, generating a vapor front that mixes with the residual inert gas in the line, usually helium. This complex two-phase/two components flow is quite challenging to model due to a lack of understanding of the physical processes taking place. A dedicated test facility that allowed for fluid transient experiments under the same conditions as an operating space propulsion system was used for tests at different conditions (tank pressure, vacuum level, geometry of the feedline) with water or ethanol [2242, 2243]. To gain detailed insight into the complex flow pattern, a transparent clear quartz segment was installed at the end of the metal feedline and high-speed images were taken. The analysis of the images provided a comparison between de-aerated and saturated conditions of the fluid, making it possible to explain the complex profile of the pressure signal. In addition, a comparison between water and ethanol showed that the differences in the flow evolution of these two fluids can be related to their physical properties such as surface tension, density, and viscosity. This has important implications when testing with the real propellant is not possible and an inert surrogate replacement fluid must be used.

Pressure transients and time to system equilibrium in a pressure-regulated liquid propulsion system due to initial system activation were evaluated using a propulsion system experimental setup with gaseous nitrogen as the pressurant and distilled water as an inert propellant simulant for hydrazine [2244]. A common liquid reservoir was used as the propellant tank, and high-pressure gas was regulated to beginning-of-life conditions. A snubber orifice was installed upstream of the regulator to protect the regulator from high-pressure transients. Experiments were performed evaluating feed pressure, tank pressure, snubber orifice diameter, and system volume. Based upon experimental results, a mathematical model was created to predict activation time for regulated propulsion systems given initial conditions. Experiments with distilled water in an existing water hammer setup using numerous different internal diameters, manifold layouts, and flow control valves, under initial atmospheric and near-vacuum pressure levels, were conducted to determine the influence of restrictions in a propulsion system, as well as the propellant manifold design, in the mitigation of the surge event maximum pressure spike levels [2245].

A feedline system has been simplified to develop a mathematical model and experiments have been carried out to verify the model [2246]. The mathematical model was developed considering a pipe of uniform cross section and a moving liquid-gas interface. Experimental studies were done using water as working fluid instead of actual propellant. The studies showed that rate of pressurization plays a very critical role on the surge flow water hammer pressure spike amplitude. Sensitivity studies have also been carried out to study the effect of density, friction, and initial liquid column length on surge flow fluid hammer pressure spike amplitude. See also [2247].

During the start-up of the propulsion system of a satellite or spacecraft, the opening of the tank isolation valve will cause the pressurized propellant to flow into an

evacuated feedline and slam against a closed thruster valve. This filling process can cause severe pressure peaks that could lead to structural failure. A very detailed investigation was conducted that would apply to all liquid propellants but is of primary interest to priming flight systems with hydrazine [2248, 2249].

A study was performed to determine the pressure transient levels in unrestricted liquid monopropellant propulsion system configurations and propellant manifolds generated from surge events during system priming, using a commercial multi-physics system-level simulation software called GT-SUITE, which predicted the maximum peak priming event pressures in various liquid system configurations [2250]. Experimental data reported in earlier research efforts involving priming after the opening of a latch valve were evaluated using the numerical model to determine the accuracy of the results among various internal diameters, line lengths, manifold layouts, and flow control valves at different pre-test pressure levels in the system. Based on the results, it was determined that the numerical model was a promising tool to predict liquid system pressure transient levels. See also [2251].

A fixed flow restriction (an orifice) in the line would decrease the liquid impact velocity, thereby reducing the water hammer. The drawback to this approach is that the system will suffer from a pressure loss during normal flow usage. A different approach would be to install a flow limiter in the propellant line. Such a device would sense an abnormally high flow and quickly close a poppet so that the orifice size is reduced. This would temporarily limit the flow velocity, thereby reducing the pressure surge. The poppet would then return to its full open position during nominal flow, thus not producing any excess pressure drop during normal operation [2252].

An experimental study was conducted to evaluate pressure transient levels in unrestricted and restricted liquid monopropellant propulsion system configurations and propellant manifolds generated by surge flow pressure spikes during a priming event. This was accomplished through the development of a priming event experimental setup using distilled water as a propellant simulant for hydrazine [2253]. The data required subsequent corrections for the different compressibilities of the two fluids. Multiple test elements were evaluated using different internal diameters, line lengths, manifold layouts, and flow control valves at atmospheric, sub-atmospheric, and low-pressure pre-test pressure levels. The goals of these experiments were to determine the influence of restrictions in a liquid propellant flow system, as well as the propellant manifold design, in the mitigation of the priming event maximum pressure spikes. Based on experimental results, it was determined that the internal diameter, line length, valve flow coefficient, and pre-test pressure level all contributed to the pressure spike magnitude of the priming event. It was also observed that peak surge pressure spike levels might be significantly minimized and equally distributed throughout a propulsion system manifold using an inline cavitating venturi and a manifold layout promoting free flow of the fluid, which was independent of the line geometry, the valve flow coefficient, and the valve opening response time.

### 8.8.2.2 Water (Fluid) Hammer Effects in Propellant Feed Systems

This section deals with pressure spikes in propellant feed systems caused not by dropping propellant into evacuated lines (surge flow and “priming” discussed in the preceding section), but these spikes are caused in lines that are already completely filled with flowing propellant when the flow is brought to a sudden halt, usually by abrupt closing of a thrust chamber valve at the downstream end of the column of moving liquid. This phenomenon occurs with all propellants and all fluids, even with water, and can cause substantial damage. Water (fluid) hammer is a strictly mechanical phenomenon and there are no chemical reactions involved, but if there are hydrazine vapor bubbles in the system (multi-phase fluid hammer), they may explode when suddenly compressed by a water hammer pressure spike. Most of the papers listed here deal with pressure spike phenomena that can occur in any moving liquid, but the pressure spikes can be disastrous if hydrazine vapor bubbles are trapped near the end of the system. Similar problems can occur with liquid oxygen (LOX), NTO, or MMH, but we summarize this phenomenon here in the hydrazine chapter.

The hydrazine monopropellant system on converted TITAN II missiles (“Commercial TITAN”) used a complement of twelve 132-N thrusters, four of these for roll control and eight for  $\Delta V$ , pitch, and yaw control. The water hammer dynamics of this system were modeled to predict and avoid unwanted pressure spikes when several thruster valves close at the same time [2254]. Similar calculations were performed for the ARIANE V SCA [2255]. Most of the computer models described here are not unique for hydrazine and can be applied to describe the flow properties of other propellants as well.

A computer code called CEDRIC was used by Matra Marconi Space to calculate predicted water hammer pressure spikes and compare them to measurements in a replica of a satellite manifold for monopropellant hydrazine [2256]. This was a simple hydraulic network but used water as the reference fluid. The researchers studied the effect of the on/off duty cycle of the thrusters on the water hammer effects when closing several valves simultaneously. They also varied line diameters, line lengths, and the tubing wall material.

The ill-fated Mars Polar Lander '98 (MPL 98) used twelve 290-N thrusters to slow its descent and come in for what was supposed to be a soft landing. Thrust chamber valves in MPL 98 provided only on-off control and were not throttleable as they had been in VIKING. Special attention was devoted to the propellant manifold filling sequence in order to prevent problems encountered several years ago when firing pyro valves in other satellites in rapid sequence. Simultaneous closing of 2 or more of the 12 TCVs may cause pressure spikes, which may damage pressure transducers, filters, or valve seats. Thorough ground testing of the MPL '98 propulsion subsystem performed with water, hydrazine, and He-saturated hydrazine showed that water hammer pressure spikes as high as 6800 kPa (1000 psi) can be encountered if several valves close at the same time. Certain duty cycles had to be eliminated to keep pressure spikes below 5500 kPa (800 psia) at certain portions of the feed system. It was feared that higher-

pressure spikes might damage the in-line filters, valve-inlet filters, or valve seats. Also, the brief low pressure upstream of the thrust chamber valves following the reflection of the pressure wave might have allowed hot gas and catalyst fines to back up into the injector or even into the valve at the start of the next pulse [2257]. During launch and cruise, lines between pyro valves and thrusters were filled with 275 kPa (40 psia) helium to maintain the cleanliness of the lines, ensuring that contaminants from the ambient atmosphere do not leak into the system. Upon arrival on Mars, prior to filling the lines with hydrazine, the manifold lines were evacuated to space by opening TCVs for 30 s, per set of four TCVs. After closing the TCVs, a bypass pyro valve was fired first, allowing flow through a narrow orifice that acted as a flow restrictor. The narrow orifice in the bypass allowed hydrazine to slowly fill the manifold to avoid pressure spikes due to surge flow and to prevent hydrazine explosion by adiabatic compression. In ground experiments with a replica of the MPL 98 plumbing system, it took less than 30 s to fill the lines, leaving a 30-s safety margin for hydrazine froth to dissipate before the next pyro valve was fired. After 60 s, the first main pyro valve was opened. After 30 s, the second pyro valve was opened. A similar orificed design and manifold filling sequence had been used successfully on MAGELLAN.

The severity of water hammering in pipeline systems varies greatly because of differences in the number and the type of thrusters and the operating time of valves [2258–2260].

The ARES I upper stage would have used a reaction control system similar to that flown on CENTAUR upper stages. Water hammer effects were studied experimentally on a replica of the ARES I upper-stage monopropellant reaction control system consisting of 2 propellant tanks and 12 thruster locations [2261]. The effect of the pressure transducer side passage conduit on the water hammer process was computed and analyzed with an example of a liquid rocket engine as the engine is shut down [2262].

Similar fluid hammer experiments were conducted with MMH, NTO, or water in the propulsion laboratory of ONERA [2263]. The objective of one study was to generate an experimental database on the multi-phase fluid hammer occurring during the priming of evacuated propellant lines with non-cryogenic or cryogenic liquids in order to understand the physical phenomena and to benchmark the numerical code Ecosim-Pro [2264]. Two dedicated test facilities (non-cryogenic and cryogenic facilities) were built at the von Karman Institute. An extended test campaign was conducted on the non-cryogenic facility to analyze the effects of various parameters on the fluid hammer behavior such as the line configuration, the vacuum condition in the line, the liquid properties, and the saturated conditions of the liquid, leading to a better understanding of the influence of the desorbed gas on the pressure spike level and attenuation. The effect of the velocity of sound with dissolved gas and the friction model would need to be improved.

The priming of feedlines during start-up of an engine as well as the rapid closing of valves upon shutdown may lead to pressure spikes symptomatic of a water hammer pressure wave. Test benches used to conduct tests on development engines as well

as currently flying engines are sensitive to water hammer pressure waves traveling along their feedlines. Different plumbing configurations were investigated to study their influence on wave shape [2265]. The configurations included a coiled pipe setup with a support structure and without a mounting anchoring support structure. A beat phenomenon (the so-called Poisson-coupling beat) was observed. It was shown that the second water hammer peak can reach pressures a lot higher than the first peak by additive interference of the primary and reflected secondary water hammer wave.

### 8.8.2.3 Theory and Modeling of Adiabatic/Rapid Compression Initiation of Hydrazine

Several attempts have been made to explain the mechanism responsible for the adiabatic/rapid compression initiation of hydrazine deflagration. Several writers have called this a hydrazine “detonation,” but measurements did not indicate a true C-J detonation. High-speed photography images of a liquid front of hydrazine rushing into a transparent cavity were highly informative in visualizing the two-phase flow condition immediately prior to explosion of the tube. It is assumed that the liquid front rushing into a straight dead-ended tube will assume an arrowhead shape since friction along the walls causes the peripheral annulus to lag behind the core flow. If a Teflon foil is used to separate the liquid and the gas prior to the test, as was done in the NASA WSTF tests, it will stretch to rupture and its cone shape will also determine the shape of the liquid-gas interface as it rushes down the test section. Once the gas that is pushed ahead of the liquid “piston” is sufficiently compressed, it will be compressed against the rigid end plug by the momentum of the advancing liquid core. The momentum of the moving liquid keeps it moving faster than the gas, even as the gas pressure is building up. At the liquid-gas interface the differential velocity is sufficiently high to cause Taylor instabilities like a storm blowing over an ocean whipping up waves and whitecaps and carrying spray droplets with it. At a certain wave height, additional liquid spray droplets are ejected into the gas flow and more gas bubbles are entrained into the liquid flow. The front of the advancing liquid assumes a frothy appearance.

CNES conducted shock-tube tests of hydrazine vapor with and without diluents to explain the compression sensitivity of bubbly liquid hydrazine [1192, 1257]. While the study provided additional data on vapor decomposition kinetics, it only cursorily discussed bubble dynamics. It did, however, provide a brief comparison of hydrazine decomposition in compressed bubbles (at high pressures) as opposed to hydrazine vapor decomposition in reflected shock waves in shock tubes. It was stated that the shock-tube method does indeed have the ability to pressurize and heat a gas adiabatically at the precise temperature and pressure conditions encountered in rapidly compressed bubbles. The investigators cautioned that the heat and mass transfer at the gas-liquid interface of entrapped bubbles must not be neglected. The increase in pressure deforms bubbles, heats the medium, and leads to additional hydrazine vaporization. Hydrazine evaporation, though a slow process, cools the surface of bubbles. At the same time, hydrazine vapor in the bubble, which was saturated to start

with, is compressed to conditions beyond saturation and would be expected to condense in the form of a mist if the temperature did not increase very rapidly due to adiabatic compression. The rate of condensation may not be fast enough to avoid forming a supersaturated gas phase.

In a two-part study to determine hydrazine explosion conditions related to the presence of bubbles in a liquid, the first part was devoted to the kinetic modeling of the thermal decomposition of hydrazine in the gas phase in the presence of diluents [2204]. The reaction behind a reflected shock wave was analyzed by absorption spectrometry between 1100 and 1400 K for shock pressures between 200 and 1350 kPa. The influence of the nature of the diluent ( $N_2$ , He) and that of additives ( $H_2$ ,  $NH_3$ ) on the reaction rate made it possible to validate a detailed kinetic model comprising 48 steps and 11 species. The second part concerned the analysis of the behavior of a bubble, trapped in water as a model fluid and in contact with a wall, by rapid imaging (framing rate of 27000 frames/s). The bubble was subjected to a compression initiated by a shock wave reflected on a membrane separating the liquid from the impact tube. The gas consisted of a stoichiometric mixture of oxygen and ethylene, diluted in argon or nitrogen, whose thermodynamic properties and characteristic reaction times were close to those of hydrazine/diluent mixtures. The volume of the bubble was between 100 and 1000 mm<sup>3</sup>. The deformation of the bubble showed that the gas/liquid interface was preserved during the first compression phase and then gradually deteriorated in the expansion phase. Explosions were observed when the ignition delay was less than the time corresponding to the first phase of compression of the bubble.

When diluent gases are present and mixed with fuels, appropriate EOSs must be selected for the diluent gases to calculate the temperatures as a result of isentropic compression of mixtures of fuels and inert gases [2266]. Reliable engineering design and safety analysis for fuel diluent gas mixtures requires correct thermodynamic mixing rules for isentropic compression analysis. Simplifying approaches such as zero- and first-degree approximations are not adequate. The presence of multiple phases over the range of conditions examined suggests that additional work on multi-component, multi-phase systems is required. At pressure ratios above 100, estimating the isentropic compression temperature at ideal conditions gave temperatures approximately 5% greater than by estimating using the appropriate EOSs.

There are a few theoretical analytical studies of compression of reactive vapor/gas bubbles suspended in a non-reactive liquid. There are a few mathematical-analytical publications on reactive bubble compression and cavitation not specifically dealing with hydrazine [2267–2270]. Many of these studies relate to the propagation of LVD detonations in bubbly media. It would be worthwhile to combine this information with the experimental data on hydrazine and determine whether a correlation could be established. Liquid hydrazine (as opposed to hydrazine vapor) is assumed not to participate in rapid compression explosion events. It would be of interest to have an analytical method to predict the critical bubble: liquid volume ratio and compression pressure ratio beyond which hydrazine becomes explosive in the form of froth or foam.

The type of gas and the percentage of vapor entrapped in bubbles would be expected to influence the threshold. We would suspect that helium (frequently used pressurant or purge gas) would make the mixture more sensitive than nitrogen/ammonia (natural decomposition products). In some cases, the collapse of a bubble will be followed by expansion and an oscillatory mode that eventually attenuates and fizzles out. On a microscopic scale, cavitation of gas and vapor bubbles in an intense ultrasound field will cause decomposition (“sonolysis”) of hydrazine [2271]. This is the subject of a new field of study called sonochemistry. This mechanism can be used for the degradation of hydrazine for the decontamination of wastewater (Section 7.12.1.12).

## 8.9 Sensitivity of Hydrazine Exposed to Pyro Valve Blow-by Hot Gases

Several studies on the effects of hot gases from blow-by of pyrotechnic actuator charges in pyro valves on hydrazine and MMH have been conducted in the wake of the losses of MARS OBSERVER (August 21, 1993), LANDSAT F (October 5, 1993), and TELSTAR 402 (September 9, 1994).

In the early 1990s, after a string of satellite and space probe failures attributed to pyro valve explosive interaction with hydrazine propellants, there began a flurry of studies on all conditions under which hydrazine propellants can be initiated to accidental explosions by activating a pyro valve. The most likely cause for the loss of LANDSAT F shortly after stage separation from the TITAN II launch vehicle in October 1993 was a ruptured hydrazine manifold. The ruptured manifold rendered the satellite’s reaction engine assemblies useless because fuel could not reach the engines. Consequently, there was a failure to maintain attitude control during the apogee kick motor (AKM) burn. This failure caused the spacecraft to tumble during the AKM burn and not accumulate enough energy to attain orbit. A few months thereafter, a communication satellite failure occurred when the second of two parallel pyro valves was fired with a programmed delay sequence into a manifold that at that time was partially filled with helium and hydrazine froth. Blow-by of hot gases from the second pyro valve past a leaking ram piston may have initiated a thermal runaway reaction in the hydrazine that ruptured the tubing. This most likely sequence of events was reproduced in simulating ground tests after flight anomalies had occurred. The results of industry-wide workshops were documented in a series of workshop proceedings. Several of these publications deal with anhydrous hydrazine and MMH at the same time, so we need to reference them in more than one location in this book [1827–1833, 2272, 2273].

The effectiveness of O-rings in pyro valves in preventing blow-by of hot gases has been questioned. Numerous publications have been issued in which post-test inspections report that O-rings sheared and shredded. Testing had shown that with some valve designs blow-by occurred regardless of whether O-rings were installed properly or accidentally omitted. As a result of lessons learned, new and improved pyro valve

designs emerged in the mid-1990s, and the pyro valve problems have not re-occurred since then.

Theoretical calculations tried to support the experimental investigations. In one of the real gas (vapor) EOS studies for rapid compression of hydrazine vapors, an attempt was made to include typical pyro valve actuator pyrotechnic charge exhaust products in the calculations [209].

A theoretical kinetic study was conducted to investigate the effects of hydrogen presence in pyro valve actuator blow-by gases on hydrazine decomposition, with some representative calculations including the remaining gaseous species found to exist in blow-by gases [1371]. Since hydrogen is a normal product of hydrazine decomposition, all reactions necessary to evaluate its effect on hydrazine decomposition chemistry were in the original developed mechanism [1372]. However, the mechanism needed to be considerably expanded to include the reactions of other gaseous blow-by species with hydrazine, with all the intermediate species formed in its decomposition, and with each other. The expanded kinetic mechanism consists of 70 species interacting via a network of 452 reactions. Calculations indicated that  $H_2$  presence as an initial reactant in substantial amounts can dramatically impact the decomposition process for hydrazine. What was of particular interest, and somewhat surprising, was the extent to which molecular hydrogen in the initial mixture was predicted to accelerate the decomposition of hydrazine. The change in hydrazine half-life from the baseline case (i.e., no  $H_2$  initially present) to the case where a 1:1  $H_2:N_2H_4$  starting ratio exists was five orders of magnitude. Earlier studies on the effect of atomic hydrogen on hydrazine decomposition [2274] should have been referenced in that study. The other gaseous blow-by species [CO,  $CO_2$ ,  $H_2O$ , C(S),  $O_2$ , and  $N_2$ ] were found to have little effect compared to the inclusion of hydrogen itself as an initial reagent. This result was due, in part, to the fact that the blow-by gas used in one case consisted of 94.6%  $H_2$ . A more rigorous examination of the behavior of the fully detailed mechanism under a variety of conditions was not performed.

### 8.10 Electrostatic Discharge Sensitivity of Hydrazine

Both anhydrous liquid hydrazine and hydrazine hydrate have been tested for sensitivity to ESDs [1408]. No noticeable decomposition was noted in unconfined samples when a static charge of 12.5 J was discharged through the liquid. With partial confinement in a plastic tube, decomposition became apparent when the spark energy exceeded 2.6 J. Sparks of higher energy caused enough decomposition to break the plastic capsule. The potential applied to the electrodes was 5000 V, and the energy was varied by using all or only a portion of the capacitor bank.

Several liquid hydrazine mixtures containing up to 30% HN and up to 30% water were tested on the NOL electrostatic sensitivity apparatus [242]. No detonation or onset of burning was obtained with sparks from 150000-pF capacitors at 5.5 kV. In addition

to the solutions, some HN crystals (which may have contained a few percent of water) were also tested on the same machine, and no explosions were observed. Submerged electric discharge sparks have also been tested as a means of deliberately initiating the decomposition of HPB-3005 hydrazine/hydrazinium nitrate monopropellants in rocket thrusters or liquid propellant guns [2275, 2276].

The minimum spark ignition energy required to initiate decomposition or explosion of hydrazine vapor has never been measured. Likewise, the ignition energy of hydrazine-air mixtures is unknown. The energy available from an automotive ignition coil is more than enough to initiate the decomposition or combustion of hydrazine vapor [1408]. Designers for propellant storage and transfer facilities should adhere to the recommendations provided in [2277].

### 8.11 Friction Sensitivity of Hydrazine

Neither hydrazine nor the 85% hydrazine hydrate showed any sign of explosion, burning, or local crackling when 10 samples each were tested in the USBM pendulum friction test apparatus using a steel shoe and a stainless-steel anvil [1408]. Whereas hydrazine liquid is not friction sensitive, some of its solid and dry salts may be quite friction sensitive.

### 8.12 Bonfire Tests with Hydrazine

Another requirement of propellant classification for transport by common carrier is the bonfire test where a shipping container filled with the material is placed on a grate on top of a pile of wood and ignited. Wood-fired or oil-fired bonfire tests with the monopropellants hydrazine, 66% hydrazine/24% HN/10% H<sub>2</sub>O, *n*-propyl nitrate, and ethylene oxide in 1-gal aluminum containers showed that all four propellants caused container explosions regardless of the type of bonfire or the amount of liquid (95% full or 25% full) in the tank [2184]. It was recommended that storage drums have rupture disks that would allow pressure relief and evaporation of the liquid before explosion pressures are reached. With hydrazine, the 25%-full container would explode after approximately 1 min, whereas it took 2–19 min. for the 95%-full container to explode. In the case of the HN-containing mixture being cooked in a container, an explosion is inevitable even after (or particularly after) all liquid has evaporated.

Another method of testing propellant hazards is the open-pool burning. This test is of importance for propellants such as MHF-1, MHF-4, or MHF-5 that contain HN. If a container or a spill of these fuels caught fire, the volatile fuel (MMH) would burn away first, and HN would accumulate in the residue until the detonable limit is reached. Samples of 250 mL MHF fuels were burned in open dishes [2278]. The initial flame was yellow in color, later turning orange. After all the volatile liquid was

consumed, the flame changed to a tall, hissing columnar flame (“flare burning”), which consumed all the solid (molten) material. In only one out of hundred MHF-1 tests the flare burning was abruptly terminated by a detonation. This effect was not reproducible. By analyzing the nitrate content in residues from tests where the burning liquid was extinguished by a blast of nitrogen before flare burning started, it could be shown that hardly any HN is consumed during the luminous flame prior to flare burning. In other tests, with boiling off of the liquid constituents by external heat (without burning) and continued heating, the residue would typically explode. In all boil-off tests the temperature reached 564–592 K at the time of explosion.

An accident review published as CPIA Publication 661 [2279] makes reference to three events, including explosion of hydrazine storage drums or propellant tanks in fires with the violent explosion of pressure vessels (near field blast) but no mass sympathetic reaction to adjoining tanks, with minimal far-field fragment hazards.

## 9 Toxicity of Hydrazine

In arguments, the toxicity of hydrazine has been cited as the reason why industry-wide (not only the aerospace industry) use of hydrazine and hydrazine hydrate should be restricted. Some overly concerned, single-minded environmentalists have even discussed eliminating hydrazine (hydrate) altogether and have started working on so-called sunset legislation for the gradual elimination of hydrazine (hydrate) from the chemical inventory. Closer examination of some of the documents issued by some of the agencies, for instance a dossier issued by REACH in Europe [2280], reveals that the authors of those reports are poorly educated and have parroted unsubstantiated claims about the hazards of hydrazine. Worldwide recognized sources of information on hydrazines were omitted. No allowance was made for the reduced toxicity of hydrazine hydrate solutions compared to the toxicity of anhydrous hydrazine.

The world’s most complete reference publication on hydrazine(s), written by the same author as the rocket propellant book at hand, in its first [11] and second editions [22], contains a comprehensive list of references on toxicity. This should be the primary source of information and at this time there is very little that needs to be added to it. The current section on hydrazine toxicity presents a condensed review of more detailed sections available in the 2001 edition of the hydrazine book [22], which did not have to be repeated here. Frequent reference to that widely recognized source of information on hydrazines may suffice.

In attempting to organize a section on the toxicity of hydrazine, different approaches can be taken: The subject matter can be grouped by mode of administration (or inadvertent absorption), the body organ affected, or the symptoms observed. The initial main part of this section is arranged by body part affected by exposure to hydrazine. This material, collected from the literature, is then supplemented by several sub-sections discussing mutagenic, oncogenic, or teratogenic effects. This

section here is similar to sections on the toxicity of alkylhydrazines in the chapters on dimethylhydrazines and methylhydrazine, and there may be some overlap. Many publications deal with more than one hydrazine at a time, so these publications are referenced individually and repeatedly in several places in this book.

For a discussion of the possible adverse effects of hydrazine in an occupational environment, such as at rocket launch sites, two types of inadvertent exposure must be considered, vapor inhalation and liquid splashes. The first type of exposure would cause predominantly respiratory and systemic effects, whereas in the latter case effects on skin and eyes must be considered in addition to respiratory and systemic effects. Accidental oral ingestion has happened but is less likely and is readily diagnosed.

As Back et al. in their reviews on the occupational hazards of missile operations involving hydrazines already pointed out, “Chemists and materials engineers are spawning new chemicals and new uses for old chemicals faster than toxicologists, pharmacologists and occupational hygiene and industrial medicine personnel can cope with” [2281–2283]. The price of increased energy content in high-energy rocket propellants has been increased reactivity and biological activity. Recent decades have seen growing concern about environmental and occupational hygiene effects of hydrazines, requiring special attention and clarification.

## 9.1 Hydrazine Toxicity Literature

A detailed summary of the literature on the toxicity of hydrazine and hydrazine hydrate was published in the second edition of the book *Hydrazine and Its Derivatives* [22] on pages 895 through 1102, and there is very little to add to this readily available and exhaustively thorough source of information.

The first source of information on many hazardous chemicals is now the Material Safety Data Sheets (MSDSs), which usually accompany every shipment of chemicals. These MSDSs need to be updated from time to time. It is useless to copy an MSDS that does not have the latest date of revision printed on it. The most recent versions of MSDSs are often available on web sites of manufacturers, distributors, or government agencies. Most recently these documents are called just Safety Data Sheets and the word Material is omitted.

A thorough and ongoing search of the literature on the safety and performance of hydrazine as a rocket propellant and energy source has been performed by the author over the past 40 years. As is evident from the years of publication of many of the references cited in the list of references, hydrazine toxicity was very actively investigated during the 1970s and 1980s, leading to repeated lowering of the allowable TLVs in the air at workplaces. Very little relevant information on hydrazine is found in textbooks and standard reference books on occupational hygiene. It is deplorable that most of these books elaborate on anhydrous hydrazine toxicity, but very few data can be found

on the industrially much more important hydrazine hydrate and hydrazine hydrate solutions. At the point of absorption into the body, anhydrous hydrazine turns into hydrazine hydrate and hydrazinium ion, two chemical species different in chemical activity from their parent, anhydrous hydrazine.

*Patty's Industrial Hygiene* is now in its sixth edition and has grown to a multi-volume work consisting of Vol. 1, *Hazard Recognition*, Vol. 2, *Evaluation and Control*, Vol. 3, *Physical and Biological Agents*, Vol. 4, *Program Management and Specialty Areas of Practice*, but does not contain individual sections dealing with one specific chemical [2284].

*Sax's Dangerous Properties of Industrial Materials* is currently in its 12<sup>th</sup> edition consisting of five volumes [2285]. These two books are standard reference sources on the bookshelf of every industrial occupational hygiene and environmental protection expert.

The book *Hydrazines and Cancer* was published in 2000 [2286]. It is a very thorough review of carcinogenicity test data with both naturally occurring and artificial hydrazine chemicals. There are a few thorough review articles and summaries on hydrazine toxicity. The most notable ones in this category are those by Toth with 326 references [2287] and Moloney with 200 references [2288]. If we had better and up-to-date summaries like these examples, we would not have had to devote an entire section of this book to hydrazine toxicity.

As a group, these review summaries in combination with the selectively expanded toxicity section in this book provide a comprehensive list of references for further in-depth study of this subject. There have been no significant new additions to this list during the past 20 years.

Several authoritative research organizations and government agencies have published toxicity summaries on hydrazines. One of the most thorough studies is the *Environmental Health Criteria*, Vol. 68, published by the World Health Organization in 1987, containing 244 references [2289]. That study benefited from the availability of the 1984 first edition of the hydrazine book by the current author, which is included in the WHO list of references. This was supplemented by the *Hydrazine Health and Safety Guide*, a somewhat shorter summary [2290].

The *Criteria for a Recommended Standard: Occupational Exposure to Hydrazines*, published by NIOSH in 1978, is no longer up to date and requires a thorough revision [2291]. Forty years ago, it represented a good starting point because it contained 229 references. NIOSH Standard 78-172 *Hydrazine* is now available on-line as a series of nine files in .pdf format at <http://www.cdc.gov/niosh/78-172.html>. When that document was still in the review stage in December 1977, the USAF Office of the Surgeon General commented on the NIOSH draft, stating that no toxicology data existed at that time to support a NIOSH-proposed lowering of the 1977 American Conference of Governmental Industrial Hygienists (ACGIH) TLVs. It also explained that in view of restrictive handling procedures used by manufacturers and DoD operations, the po-

tential for routine chronic exposures was limited and the total number of potentially exposed personnel was small.

The US Environmental Protection Agency has published *Health and Environmental Effects Profiles* for hydrazine and hydrazinium sulfate [2292]. These represent useful summaries for someone just starting out in this field or someone trying to get a perspective on the history of hydrazine toxicity studies. An attempt was made to establish a carcinogenic potency factor for all three propellant hydrazines, hydrazine, MMH, and UDMH. Other toxicity data have been collected in a four-page hazard summary [2293].

A sub-committee of the German Society of Chemists (GDCh) has published a very detailed toxicity summary on hydrazine, hydrazine hydrate, and hydrazinium sulfates that contains several pages of references [2294].

A very comprehensive source of toxicity data for *all* chemicals (including hydrazines) is the Registry of Toxic Effects of Chemical Substances (RTECS) [2295–2298]. RTECS is a subscription-only database of toxicological information compiled, maintained, and updated by the National Institute for Occupational Safety and Health. Since 1971, the list has continuously grown and been updated. As of 2001, RTECS contained over 133000 chemicals as NIOSH strives to fulfill its mandate to list “all known toxic substances and the concentrations at which toxicity is known to occur.” RTECS provides identification of six types of toxicity data, including primary irritation, mutagenic effects, reproductive effects, tumorigenic effects, acute toxicity, and other multiple-dose toxicity. It includes specific numeric toxicity values such as LD<sub>50</sub>, LC<sub>50</sub>, TDLo, and TCLo.

More curious readers will appreciate references directing them to a few good starting points for more detailed studies. Many of these toxicity summaries are specifically on the use of rocket propellant hydrazines, which includes the methylhydrazines [2299–2303].

Several of the toxicity summaries were prepared by government agencies in trying to establish safe occupational exposure limits for hydrazines [2291, 2304], as well as for astronauts in closed environments, such as in spacecraft [2305].

When reviewing results from various experimental investigators, it was often very difficult to give a comprehensive survey that was free from contradictions. Even scientists who have studied toxicology their entire lives are often frustrated by the ambiguity and contradictions in many published reports describing the hazardous effects of chemicals [2306]. All carcinogenesis/epidemiological investigations in humans can be criticized because either too few patients were used or because the observation period was too short, since the latency of cancer could be 20, 30, or 40 years after exposure. It becomes apparent that toxicology is not an exact physical science, and statistical ground rules in experiment design and interpretation of data have not always been obeyed. This book can unfortunately offer only a mere juxtaposition of reported results, contradictory or not. The group consisting of hydrazine and its alkylated derivatives is often referred to in the plural case as *hydrazines*. In many instances,

hydrazine derivatives become hydrolyzed or oxidized in the body and hydrazine itself becomes an intermediate in their metabolism.

Until 1995, commercially available anhydrous hydrazine in the US usually contained 0.3 to 0.4% aniline. The initial aniline content was substantially higher when anhydrous hydrazine first became available in the late 1950s. It was noted that some toxicity investigators used commercially available anhydrous hydrazine and made dilutions from it to inject or feed to animals. Some investigators may not have known that the hydrazine contained aniline as an impurity. It is not known what effect the presence of aniline might have had on the results of animal tests conducted in the early years. On the other hand, if the toxicity test was performed to assess the hazard to propellant handlers at missile launch sites, it was appropriate to use the same fuel that the personnel might be exposed to. Aniline is less volatile than hydrazine, and its vapor concentration would not have been very high.

The USAF, as one of the main users of propellant hydrazines, has conducted a long series of toxicity studies and published the results in a series of reports that are summarized in a bibliography [2307]. Toxicity problems with hydrazines are minor compared to problems that would have to be anticipated with other, more energetic propellants like boranes and halogen fluorides that at one time were also considered rocket propellants [2308].

Hydrazine  $N_2H_4$  itself has the lowest vapor toxicity potential of the most frequently used hydrazine fuels. This is illustrated in Table 91 and Figure 68, which show a comparison of hazard indices for various rocket propellants and automobile fuels. More volatile liquids are more likely to cause accidents than less volatile liquids. The *hazard index* is often defined as the quotient of vapor pressure at ambient temperature and the  $LC_{50}$  (lethal concentration at which 50% of the test animals survive). The hazard index addresses only the most immediate acute toxicity hazard. In the format shown here for comparison only, it does not address chronic health hazards resulting from long-term exposures to even much lower concentrations. The

**Table 91:** Hazard indices of hydrazine and methylhydrazines.

| Compound                                | Formula         | Vapor pressure at 298 K<br>(25 °C = 77 °F), mm Hg | $LC_{50}$ , 4 h,<br>ppm | Hazard index,<br>mm Hg/ppm |
|-----------------------------------------|-----------------|---------------------------------------------------|-------------------------|----------------------------|
| Hydrazine                               | $N_2H_4$        | 14.4                                              | 570                     | 0.03                       |
| Methylhydrazine                         | $CH_3NHNH_2$    | 49.6                                              | 74                      | 0.67                       |
| Unsymmetrical<br>dimethylhydrazine      | $(CH_3)_2NNH_2$ | 156.8                                             | 252                     | 0.62                       |
| Symmetrical<br>dimethylhydrazine        | $CH_3NHNHCH_3$  | 69.9                                              | Avg. 340                | 0.21                       |
| For comparison:<br>Dinitrogen tetroxide | $N_2O_4$        | 875                                               | 67                      | 13                         |

Data source: [2309]

**Figure 68:** Hazard index of hydrazines in comparison to other propellants.

hazard index relates somewhat to the Immediately Dangerous to Health and Life concentrations defined in Section 9.11.5.

The toxicity of hydrazine and its derivatives is of interest from both a therapeutic (side effects of hydrazine-derived drugs), epidemiological (side effects of plant growth retardant residues in food for human consumption), and an occupational hygiene point of view. In recent decades, an increasing number of chemicals, even some of those encountered in daily use, have been identified as carcinogens and potential carcinogens. Accordingly, much work has been devoted to studying the carcinogenic (or oncogenic) potential of hydrazines (Section 9.7). See also [2310, 2311].

## 9.2 Observed Symptoms as a Result of Hydrazine Exposure

This section on symptoms observed as a result of hydrazine poisoning represents a summary and introduction that is intended mostly as a warning to someone who is trying to prevent (or a guideline to someone who is trying to explain) certain symptoms observed in humans and animals with a history of exposure to hydrazines. Obviously, most of the data compiled here were obtained on test animals. Few reports exist on symptoms observed in humans following accidental exposures. For the sake of brevity, the species in which the symptoms were observed, the mode of administration, the concentration of the toxicant, and the duration of the exposure details are not yet provided in this initial summary. Details on the exposure conditions can be found in the individual subsections following this introduction. These individual subsections are subdivided by the part of the body affected by exposure to hydrazine. As with many other toxic substances, the response may be species-dependent or even

strain-dependent. For instance, hydrazine may cause cancer in one species of test animal but not in another. Unfortunately, some of these disputes about contradictory results could not be resolved while this book and previous books were in preparation, and the reader may sometimes find a juxtaposition of contradictory data without a clear conclusion. The numbers in parentheses following the listed symptoms refer to the ensuing paragraphs in which these symptoms are discussed in more detail.

One of the prime target organs of poisoning by hydrazine and hydrazine derivatives is the liver [2312–2319]. Symptoms include fatty degeneration of liver tissue, centrilobular damage, changes in glycogen content, and loss of mitochondrial activity. In the blood, hydrazine hemolyzes red blood cells [2320]. Numerous enzymes are disturbed by the presence of hydrazines. The metabolic pathway of hydrazines can be traced by a number of experimental toxicokinetic techniques that help to explain the observed symptoms. Symptoms in the kidney and urinary tract that were caused by hydrazine(s) included changes in creatinine clearance and rate of glucose resorption [2321–2327]. Other symptoms caused by hydrazine include increased diuresis, salivation, hyperventilation, vomiting, diarrhea, and increased neuromuscular activity.

In summary, as depicted in Table 92, a variety of symptoms are observed as a result of hydrazine poisoning, but to a different degree depending on which hydrazine caused the problem. Some of the symptoms are not quite as severe with hydrazine itself as they are with methylhydrazines. The simple table tries to give an overview of symptoms observed with the four most commonly used hydrazine compounds. A single plus (+) sign marks cases where specific symptoms were observed. Two plus signs (++) identify conditions where these symptoms are always very strongly observed. A question mark (?) indicates that the information gathered was inconclusive. The table cannot be detailed enough to take into consideration the

**Table 92:** Summary of adverse effects of hydrazines.

| Adverse effects     | Symptoms observed                     | N <sub>2</sub> H <sub>4</sub> and N <sub>2</sub> H <sub>5</sub> OH | MMH | UDMH |
|---------------------|---------------------------------------|--------------------------------------------------------------------|-----|------|
| Respiratory effects | Nose and throat irritation            | +                                                                  | +   | +    |
| Respiratory effects | Tracheitis and bronchitis (secondary) | +                                                                  |     |      |
| Respiratory effects | Pulmonary edema                       |                                                                    | +   |      |
| Systemic effects    | Dizziness and nausea                  | +                                                                  | ++  | ++   |
| Systemic effects    | Anorexia                              | +                                                                  | +   | +    |
| Systemic effects    | Fatty degeneration of the liver       | ++                                                                 | +   | ?    |
| Systemic effects    | Degeneration of the kidneys           | +                                                                  |     |      |
| Systemic effects    | Methemoglobinemia                     |                                                                    | ++  | +    |
| Systemic effects    | Convulsions and stupor                | +                                                                  | ++  | ++   |
| Systemic effects    | Tumors                                | ?                                                                  | ?   | ?    |
| Skin effects        | Skin edema                            | +                                                                  |     |      |
| Skin effects        | Allergic dermatitis                   | +                                                                  |     |      |
| Eye effects         | Itching, burning, and swelling        | +                                                                  | +   | +    |
| Eye effects         | Cornea damage                         | ++                                                                 |     |      |

variation of species in which these symptoms were observed (e.g., mouse, rat, dog, monkey), nor does it differentiate between different durations or concentrations of exposure.

### 9.3 Metabolic Fate of Hydrazine

Many of the symptoms and effects caused by hydrazine discussed in this section are caused by the interference of hydrazine with metabolism in the various organs attacked. It is sometimes difficult in summarizing a large amount of data to separate the cause and effects of hydrazine on metabolism in some specific target organs. The more academic studies on the metabolic actions of hydrazine and the effects on certain target organs have already been summarized in other publications [22] and are not repeated here. Often the metabolic action of hydrazine is compared to the action of methylhydrazines, which are also used as rocket propellants.

Besides observing the adverse effects of hydrazine on various parts of the body, it is also of interest to determine which pathways hydrazine and its derivatives follow through the body and what fraction is excreted unchanged or as intermediate additive with other metabolites or totally metabolized to nitrogen and water [2328, 2329]. In addition, toxicokinetic studies have looked at the rate at which the poison is distributed throughout the body and at what rate it disappears through either metabolism or clearance in the unadulterated state.

Many of the early studies of metabolic pathways were done by identifying agents that could block a vital step of a metabolic cycle, then observing which metabolic substrates accumulated when the blocking agents were administered to living animals. Hydrazines and hydrazides were once studied in this way, until radioactive tracer techniques became available that allowed investigators to keep track of individual molecules as they moved through the body.

The reactions that hydrazine and its derivatives undergo in the human body can be grouped into non-enzymatic reactions, transferase reactions, hydrolase reactions, and redox reactions. The tracing of the metabolic pathways of hydrazines by the chemical analysis of body fluids and excrements is very difficult because hydrazines are so reactive. Important biotransformation reactions include hydrazone- or azine-forming reactions with carbonyl compounds, acetylation, hydrolysis, and oxidation. The biochemical pharmacology of hydrazine and hydrazine derivatives is a topic that has received extensive research attention in recent decades [2330, 2331]. Hydrazines can be bioactivated, leading to intermediates of increased reactivity [2332].

The metabolic fate of hydrazine(s) is independent of the mode of administration since blood acts as the transport vehicle in most cases. Resorption through the skin may be different from the other methods commonly used for administering experi-

mental drugs and poisons. The skin is a very inefficient barrier to hydrazine liquid splashes or hydrazine vapors, and hydrazine toxicokinetics after skin permeation are the same as if it were administered by other methods [2333].

Interspecies variation for hydrazine toxicity between rats and mice has been studied by administering hydrazinium(1+) chloride *po* to rats (30 mg/kg,  $n = 10$  and 90 mg/kg,  $n = 10$ ) and mice (100 mg/kg,  $n = 8$  and 250 mg/kg,  $n = 8$ ) [2334]. The direct biochemical effects of hydrazine in kidney, liver, and brain tissue were assessed in male Sprague-Dawley rats using NMR spectroscopy [2335]. Of special interest are reactions involving hydroxyl free radicals during the oxidative metabolism of hydrazine derivatives, since some of these compounds may lead to cancer.

Non-enzymatic reactions as part of hydrazine metabolism are those that are most easily reproduced *in vitro*. Hydrazines have a pronounced affinity to carbonyl groups in sugars and other compounds essential for living cells. The reaction of hydrazine with amides, whether singular amides or polymeric amides such as peptides, leads to the hydrazinolysis and breakage of the peptide chain. The hydrazine metabolism of microsomes (i.e., protoplasmic granules) is easily studied *in vitro*. It has been demonstrated that hydrazine is metabolized by rat liver enzymes located in the microsomal fraction.

Efforts to track the movement and location of hydrazine in body fluids are hampered by the reactivity of hydrazine and by the interference of biogenic amines in the analysis of trace hydrazine. Early studies on the excretion of hydrazines and metabolites used a gasometric method for determination of the sum of hydrazine and hydrazine derivatives in urine. The sample was reacted with potassium iodate in a Warburg apparatus or van Slyke apparatus, and the amount of nitrogen collected was measured.

Mass spectrometric analysis of exhaled air showed that 15% of a single dose of  $^{15}\text{N}_2\text{H}_4$  administered to rats was converted to  $^{15}\text{N}_2$  gas and exhaled within 30 min. after gavage. An additional 10% emerged within the subsequent 48 h [2336–2340]. Later studies [2341, 2342] eventually confirmed the presence of  $^{15}\text{NH}_3$  in urine.

When following the time dependence of tissue levels and excretion of hydrazine as measured by reaction with PDAB and spectrophotometry, hydrazine continued to appear in the urine of mice and rats for 20 h or more after a single injection [2343–2345]. Significantly high levels of all hydrazines and especially acetylhydrazine were detected in the kidney. The excretion of hydrazine and acetylhydrazine in the urine were dose dependent: The proportion of hydrazine and acetylhydrazine excreted declined with dose [2346, 2347].

A study of Japanese workers exposed to hydrazine (hydrate) vapors in an industrial setting, where the exposure level was  $\sim 0.1$  ppm  $\text{N}_2\text{H}_4$  in air, revealed that the workers excreted an average of  $2.7 \pm 2.0$  ppm ( $n = 8$ ) hydrazine in their urine [2348]. Humans differ in the rate at which acetylation occurs in their metabolism. Based on this study, occupational exposures are expected to produce urine excretions

greater than 1 ppm hydrazine and it may be possible to establish a biological activity index [2349]. Tracing the pathway of  $^{15}\text{N}_2\text{H}_4$  isotope-labeled hydrazine through rats by collecting urine specimens, lyophilizing, and analyzing them by NMR led to the identification of several new hydrazine metabolites [2342]. Ammonia and unchanged hydrazine were readily identified in the inorganic portion. Acetylhydrazine and diacetylhydrazine (known from previous studies) were readily confirmed. Carbazic acid, pyruvate hydrazone,  $^{15}\text{N}$ -enriched urea, and cyclic 2-oxoglutarate hydrazone had not been reported previously but were lately discovered and identified by their NMR spectra.

#### 9.4 Therapy and Prophylaxis of Hydrazine Poisoning

Although acute or chronic poisoning by hydrazines is quite rare, a significant amount of work has been devoted to the search for antidotes against accidental or experimental hydrazine poisoning. One objective in these studies was to alleviate undesirable side effects of hydrazine-derived drugs, such as INH. In many cases, the chemicals that were found to be effective antidotes also supported previous theories about the point of attack of hydrazine in metabolism. Some amino-type therapeutics may compete with hydrazine for a site or sites on cell membranes where an attack might otherwise occur. In other cases, makeup replacement is needed for carbonyl compounds that were tied up by hydrazone formation.

Handbooks on first-aid treatment for accidental poisonings in humans unfortunately do not adequately reflect the amount of study and the large amount of information available on the treatment of hydrazine poisonings, most of which has been summarized in the preceding sections. One handbook recommended chlorpromazin or barbiturates for the treatment of hydrazine-induced spasms in human patients [2350].

The USAF AFOSH Standard 161-13 (26 Dec 1979) on page 30 stated, "If convulsions occur, diazepam or a short-acting barbiturate with due regard for the CNS depressant effect of Hz. The use of pyridoxine in advanced CNS involvement is controversial. It does not appear to be helpful in prophylaxis of CNS symptoms." A more recent revision, when Std. 161-13 was incorporated into AFOSH Std. 48-8 (1 Sep 1997), omitted this section altogether.

Propellant handling personnel should undergo routine periodical health examinations and their medical records need to be reviewed for slow changes in body functions. Considerable information that is useful in evaluating the adequacy of control measures can be obtained by compiling and analyzing clinical laboratory results, physical findings, and subjective complaints. A detailed treatment procedure for victims of acute exposures to hypergolic fuels or oxidizers has been described [2351].

## 9.5 First Aid and Clinical Treatment of Hydrazine Poisoning

### 9.5.1 Human Accident and Treatment Histories of Hydrazine Exposures

Anyone reading about the results of various experimental animal studies dealing with prophylaxis and therapy of hydrazine poisoning using pyridoxine = vitamin B<sub>6</sub> may still have some doubt as to whether this chemical would help in human accident situations. Section 9.9.2 contains a summary of hydrazine accidents and several accounts of successful application of pyridoxine therapy of hydrazine poisonings. The reader should consult that section to obtain additional information on the circumstances of these accidents. A brief summary of the pyridoxine aspects follows here. There are two cases of acute accidental hydrazine/UDMH poisonings in rocket test technicians. In these cases, timely administration of pyridoxine•HCl brought about immediate improvement of the condition of the accident victims [2352]. After injecting 200 mg *iv* and 2 × 200 mg *im* pyridoxine hydrochloride, all nervous disorder symptoms except chest congestion vanished within 20 min. Another technician caught in the same leak had hyperactive reflexes, high respiration rate, and bilateral pulmonary edema. He also was given 200 mg *iv* plus 2 × 200 mg *im* pyridoxine•HCl. His dyspnea improved, and his other symptoms abated. Follow-up studies over subsequent days and weeks showed no permanent ill effects in any of the two patients. In another accident at the same test installation, four workers suffered severe nausea and vomiting, which possibly could have been prevented by the immediate use of pyridoxine. This drug was only later administered *iv* at the onset of vomiting, and the vomiting stopped in 20 min.

A 36-year-old man was admitted to a hospital 2 h after an industrial hydrazine explosion [2353]. Burns of second and third degree covered 22% of the body surface. Fourteen hours after the burn the patient became comatose and remained unresponsive for 60 h. A decision was then made to try 600 mg pyridoxine *im* and an additional 1.0 g pyridoxine as a continuous infusion over 3 h. Four hours after the initiation of therapy, the patient began to recover, and 12 h later he was alert. The patient was discharged after 38 d (after completion and healing of skin replacement graft surgery). This case suggests the more immediate use of pyridoxine in treatment of hydrazine poisonings. In another, though less severe, accident, a 24-year-old man accidentally swallowed a mouthful of hydrazine and immediately became confused, lethargic, and restless [2354]. Three days after admission to the hospital he remained confused, but stable, until his liver function degenerated. The patient was treated with a megadose of 10 g pyridoxine *iv* over a period of a few hours. Within 24 h, the patient's mental status improved, and liver function tests returned to normal within 5 d after therapy, when he was discharged from the hospital. The patient later returned with sensory neuropathy problems, which may have been caused by the megadose of pyridoxine.

Hydrazine sulfate caused severe encephalopathy in a patient after taking 180 mg hydrazine sulfate/day for 2 weeks followed by 360 mg/d. After receiving 5 g *iv* pyridoxine in the emergency room, the patient's encephalopathy resolved within 24 h after receiving pyridoxine. High-dose pyridoxine was shown to be an effective treatment

to reverse encephalopathy and hydrazine poisoning [2355]. Pyridoxine was also useful in treating human tuberculosis patients that had suffered adverse reactions to the hydrazine-derived anti-tuberculosis drug isoniazid.

Recommended best practices for emergency medical treatment of military personnel in cases of hydrazine exposure have been reviewed [2356]. Unfortunately, only NASA and hydrazine manufacturing facilities stock necessary amounts of *iv* pyridoxine in their first-aid dispensaries, and most military medical treatment facilities have no *iv* pyridoxine in stock.

### 9.5.2 Antidotes for Treatment of Hydrazine Poisoning Tested in Animals

Antidotes against hydrazine poisoning tested in laboratory animals at one time or another include mixtures of arginine glutamate,  $\alpha$ -ketoglutarate, and oxalylacetate [2357, 2358]; sodium  $\alpha$ -ketoglutarate [2359]; sodium pyruvate and sodium salt of  $\alpha$ -ketoglutaric acid as prophylacticum and therapeuticum [2360–2362]; arginine and ornithine [2363, 2364]; arginine enhanced by L-glutamate and L-alanine [2365] or  $\alpha$ -ketoglutarate and oxalacetate [2366]; fructose [2367]; and diphenylphenylenediamine [2368, 2369]. Sodium phenobarbital in sub-hypnotic amounts was found to increase the survival rate in mice poisoned by hydrazine [2370].

Only those amino acids that take part in the urea cycle and can decrease the amount of ammonia formed primarily from hydrazine are capable of providing protection against hydrazine toxicity [2357, 2358, 2371]. Citrulline exerted no protective action, while 1,3-diaminobutyric acid and 1,2-diaminopropionic acid and several diamines did.

Pyridoxine and phenobarbital were tested as a treatment of Aerozine-50 poisoning [2372, 2373] and all hydrazines as a group [2351, 2352]. See also [2353, 2354]. Arginine or L-glutamate or pyridoxine alone did not give any noticeable protection against the toxicity of Aerozine-50 [2374]. Pre-treatment of male mice with 6 mmol/kg of arginine given *ip* or *iv* at 30 min. or 18 h prior to hydrazine hydrate injections did not have the expected prophylactic effect against poisoning by hydrazine hydrate [2361].

Two-dimensional paper chromatography was used to study amino acid distribution in tissues of normal mice, mice treated with hydrazine, and mice pre-treated with protective amino acids prior to injection with hydrazine [2375, 2376]. Glucogenic amino acids were tested as a means to reduce chronic hepatic injury induced by hydrazinium sulfate when it was evaluated as a carcinostatic agent [2377].

Eighteen different compounds were tested for their therapeutic effect against hydrazine, MMH, or UDMH poisoning (*ip*, mice) [2363]. Of those found to be effective, arginine and ornithine provided clear-cut protection from death and convulsion caused by otherwise fatal hydrazine doses, but the two amino acids were ineffective against MMH or UDMH. Amino-oxyacetic acid or pyridoxine provided effective protection against MMH or UDMH poisoning but were ineffective against hydrazine.

Only partial protection against UDMH was offered by *p*-nitrobenzaldehyde or *p*-chlorobenzaldehyde.

In one study, 0.5 mM (3.65 g/kg) of  $\alpha$ -ketoglutaric acid as the sodium salt was administered orally to mice 30 min prior to an otherwise deadly oral dose of 100 mg hydrazine/kg, and this pre-treatment permitted 95% survival [2359, 2378]. The protective efficiency of pyridoxal and other forms of vitamin B<sub>6</sub> has been disputed and questioned [2362]. In tests with rats, these compounds either had no effect on the toxicity of hydrazine or even enhanced the seizure incidence over that found in animals receiving hydrazine alone. In rats, the *in vivo* formation of pyridoxal phosphate was impeded by hydrazine administration [2379]. It has been suspected that one of the modes of toxic action of hydrazine might be the displacement of the guanidino group of arginine by hydrazine. Therefore, if enough arginine is offered in excess of that altered by hydrazine, the toxicity of hydrazine might be reduced.

Hydrazine in mice *ip* at 3.5 mM/kg caused 100% mortality, and at 3.0 mM/kg the mortality rate was 75% within 60 min. [2362]. A dose-response curve was used to illustrate the protective effect of simultaneous administration of arginine at 6 mM/kg. Arginine significantly reduced mortality rate due to hydrazine toxicity in mice (from 75 to 20%) as well as rats. Administration of 50 mg nicotinoyl-D,L-methionine/kg reduced the hydrazine liver toxicity in rats given daily injections of 2  $\mu$ M/kg of a hydrazine salt [2380].

Vitamin E ( $\alpha$ -tocopherol acetate) and vitamin B<sub>6</sub>, especially in combination, were very effective in preventing liver dystrophy in rats exposed to hydrazine [2381–2383]. Combined administration of the vitamins increased the biliation and increased the rate of cholate synthesis and cholesterol and bilirubin excretion. There are numerous studies on the therapeutic effectiveness of pyridoxine or pyridoxal against consequences of hydrazine poisoning [2384–2391].

## 9.6 Acute Hydrazine Toxicity and Inhalation Toxicity

This section contains a summary of acute toxicity studies with experimental animals. Most of these studies were done for inhalation toxicity, which was expected to be the most likely mode of accidental entry for accidents with humans in places where hydrazines are manufactured and used.

### 9.6.1 Acute Hydrazine Inhalation Toxicity Studies

This section contains more diverse toxicity data than the heading indicates. The borderline between acute and sub-acute to chronic toxicity is not a fine line and is dependent on many variables. We decided to draw the line between acute (short-term) and chronic (long-term) exposure at 1 d. The assumption is that if accidental exposure occurs due to a leak, it should typically be detected after 1 d (at the latest) and corrective

action should have been taken to correct the intolerable situation. Of course, toxicity response is species dependent, and it may not always be justifiable to extrapolate from animal test results to predicted safe levels for human exposure [2392]. Since inhalation is the most likely pathway for hydrazines in accidental poisoning of humans, these data are discussed here first. Unfortunately, of all modes of administration, controlled inhalation concentration levels are the ones most difficult to maintain in an animal experiment because hydrazines are so reactive and may autoxidize in the air of the exposure chamber or may be absorbed by the fur of the animals or the bedding materials in the cage or by the food. In some instances, 96–99% of hydrazine metered into the air stream was decomposed or adsorbed after a single pass through the exposure chamber with or without dead or living animals. There is typically more scatter and less confidence in inhalation data than those obtained with other modes of administration, such as injection. The objective of these tests is to obtain a toxicity rating and to determine threshold levels below which no toxic symptoms can be observed. Because of the large variations in individual susceptibility, statistically large numbers of animals must be used in order to arrive at reliable numbers. The data are analyzed using statistical methods, typically a probit plot, in the dose-response relationship, from which then a lethal concentration 50 (LC<sub>50</sub>) or lethal dose 50 (LD<sub>50</sub>) can be derived [2392]. This number indicates the concentration or dose at which 50% of the animals in an exposed group will survive after a stated observation period. Quite often, investigators will report the duration of exposure but will fail to specify the post-exposure observation period within which fatalities were counted. Concentrations given in ppm are independent of the temperature, which makes it more convenient to use, since the temperature does not have to be listed all the time. Concentrations in mg m<sup>-3</sup> are temperature dependent. If the temperature is not listed, it is assumed that the data are for 298 K. It is more convenient to use mg/m<sup>3</sup> units if the toxic vapor arises from evaporation of a liquid and the amount of liquid that has evaporated can be weighed. To convert from ppm (by volume) to mg/m<sup>3</sup> at 298 K and vice versa, use the following equations:

$$\text{TLV (mg/m}^3\text{)} = \frac{(\text{TLV (ppm)})(\text{molecular mass (dalton)})}{24.45}$$

$$\text{TLV (ppm)} = \frac{(\text{TLV (mg/m}^3\text{)}) \times 24.45}{(\text{molecular mass (dalton)})}$$

A summary of hydrazine inhalation toxicity and acute toxicity data is available in [2393].

#### 9.6.1.1 Acute Hydrazine Inhalation Hazard Studies

**Hydrazine Vapors.** Because hydrazine vapor may be absorbed into the body not only by inhalation but also by skin permeation, early acute toxicity studies were not able to differentiate between the two pathways. Rodents often lick their fur. Quite often hydrazine would condense on the fur of rodents in the exposure chamber and provide

an additional pathway for intoxication, which would not be typical for workers who change work clothes and take showers more often. Another uncontrolled additional mode of ingestion is the hydrazine that condenses on the food or is absorbed from the atmosphere into the drinking water and then ingested by animals.

Test protocols are often inadequate to reconstruct how long food and water has been sitting in exposure chambers. Food sitting in a chamber becomes saturated with hydrazine(s). For instance, the Vernot and MacEwen study stated that **“Introduction of considerable excesses of hydrazine was required to attain the desired analytical concentrations.** Mean nominal concentrations of 21, 5.5, 3.1, and 1.9 ppm were generated to attain time-weighted average analyzed intended concentrations of 4.96, 1.00, 0.25, and 0.05 ppm, respectively” [2394]. Clearly, several loss mechanisms consumed hydrazine that was not being inhaled. Thus, for the 0.05-ppm case, **a 38-fold excess of hydrazine over and above the intended concentration was introduced.** It must be assumed that the difference between the hydrazine introduced and the hydrazine leaving the chamber in air samples was absorbed into the skin of animals and into the food in addition to the hydrazine that was intended to be incorporated through inhalation. The food and drinking water were not analyzed for adsorbed hydrazine in these tests. The test conditions used at the University of California, Irvine (UC Irvine) constitute overly severe exposure conditions for a true respiratory hazard evaluation. The conditions do not relate to the exposure of workers in the workplace under real-world conditions. It is difficult to set up the animals such that they breathe only adulterated air and eliminate all other routes of ingestion by way of skin absorption, licking their fur, and absorption of hydrazine into food and drinking water. Workers exposed to hydrazine vapors at work are unlikely to store and eat their sandwiches and leave beverages sitting open in the same atmosphere in which they work.

One of the worst-case scenarios is a test where groups of six rats each were exposed to saturated (!) hydrazine vapors at the saturation partial pressure (14.2 mm Hg) at 298 K in air, corresponding to approximately 18600 ppm [2395]. Exposure durations were 0.5, 1, 2, and 4 h, and mortalities were very high. Examination of nasal passages revealed acute catarrhal rhinitis. Autopsy showed pulmonary edema in addition to the destruction of bronchiolar mucosa. Backing off to more moderate concentrations of 300, 76, and 26 mg/m<sup>3</sup> for 6 h/d, 5 d/week for a total of 6 weeks simulating chronic exposure conditions still resulted in some deaths in each of the 3 groups of 20 rats each. Half of the animals had perished after 27, 50, and 144 h. Lungs, livers, spleen, and kidney showed pathological changes after less than 4 d of exposure.

It appears that some of the early investigators (Vernot et al.) used a single central hydrazine analyzer with excessively long plastic hose sampling lines leading to a gallery of many exposure chambers. Hydrazine decay, permeation, and adsorption on the surface of the sampling train were ignored, resulting in possibly excessively high(er) actual hydrazine concentrations at the point of exposure of the animals. A USAF-sponsored workshop in 1990/1991 attended by participants from NASA, USAF-SD, the Navy, and the Chemical Manufacturer's Association recommended

a re-evaluation of the hydrazine vapor generation system and the monitoring used in the Vernot studies, but results of the re-evaluation have never been published.

More than 50% of a group of rats exposed to the extremely high concentration of  $20 \text{ g/m}^3$  hydrazine vapor in air for 2–4 h died during the experiment [2396]. Periodic daily exposures to lower concentrations in air, 6 h/d for 6 weeks, caused porphyrinuria, 10–20% weight loss, and pulmonary edema. The lowest concentration at which damage was detected in rats was  $26 \text{ mg/m}^3$ . Dogs exposed to  $6 \text{ mg/m}^3$  hydrazine vapor in air for 6 months got used to the toxic challenge after initial weight loss and muscle tremors. The autopsy of dogs after the 6-month test showed necrotic destructions of liver and kidney and biliary engorgement.

One of the earliest inhalation studies in 1954 also initially used excessively high vapor concentrations ( $20000 \text{ mg/m}^3$ ) for exposure periods with rats from 0.5 to 4 h, but quickly retreated to less toxic concentrations to simulate more closely the potential exposure profile of soldiers accidentally exposed to rocket propellant fumes on the battlefield [2397]. Based on these crude tests, it was estimated that the maximum allowable concentration would be below  $6 \text{ mg/m}^3$  (5 ppm).

More recent inhalation toxicity studies with rodents therefore attempted to separate the two effects by either allowing the animals to breathe the hydrazine-laden air through a mask or by placing them in a hydrazine vapor exposure chamber but allowing them to breathe clean air through a mask. Such skin permeation effect studies are discussed in Section 9.6.4.1.

The oncogenic potential of hydrazine inhalation was examined after 1 (acute) or 10 (subchronic) 1-h weekly animal exposures, and a variety of acute toxicity problems were noted [2398]. The objective of this study was to investigate the relationships of acute and sub-chronic effects of hydrazine to nasal tumorigenesis. In Type 1 (acute and sub-chronic) and Type 2 (lifetime experiments), groups of male and female Fischer 344 rats and male Syrian golden hamsters were exposed by inhalation to 0, 75 (Type 2 only), or 750 ppm hydrazine for single (acute) or 10 (sub-chronic) 1-h weekly exposures. Groups of rodents were euthanized 24 h after exposure Nos. 1 and 10 and also 24 to 30 months after study initiation. Significant reductions in body weight were observed in hydrazine-treated rodents compared to controls during the exposure interval, but none of the animals died as a result of hydrazine-induced mortality. Histopathologic examination after the acute and subchronic exposures revealed degeneration and necrosis of transitional, respiratory, and olfactory epithelia in the anterior nose and, in rats exposed sub-chronically, squamous metaplasia of the transitional epithelium. Minimal to mild rhinitis resulted from hydrazine exposures. Apoptosis was observed in olfactory and squamous metaplastic transitional epithelium. Lesions occurred at sites having high air flow and generally appeared to be more severe in the anterior portion of the nose. By 24 months, the squamous metaplastic transitional epithelium had reverted back to normal-appearing transitional epithelium. After 24+ months, low incidences (sexes combined) of hyperplasia (5/194, 2.6%) and neoplasia (11/194, 5.7%) were detected, principally in the transitional epithelium of

the rats exposed to 750 ppm. A similar incidence of hyperplasia (2/94, 2%) and neoplasia (5/94, 5.3%) was detected in the high-exposure group of hamsters. The location and type of hydrazine-induced proliferative lesions were similar to those reported in a chronic hydrazine exposure study (5.0 ppm  $\times$  6 h/d  $\times$  5 d/week for 1 year) conducted in the same laboratory, but the chronic study had much higher incidences (rats, sexes combined: hyperplasia 15.5% vs. 2.6% and polypoid adenoma 44.6% vs. 5.2%). The product of concentration  $\times$  time was the same (750 ppm h) for the high-dose groups for both studies, but the duration of exposure was 150 times longer and the concentration was 150 times lower in the chronic study. The oncogenic (long-term) aspects of this experiment with rats and hamsters are discussed in more detail in Section 9.7.

Male and female Sprague-Dawley rats (five animals/sex/group) were exposed (nose only) for 1 h to an aerosol of hydrazine (64% aqueous solution, equivalent to 100% hydrazine hydrate, mass median aerodynamic diameter  $\pm$  geometric standard deviation of  $5.0 \pm 2.56$ ,  $1.1 \pm 3.56$ ,  $1.8 \pm 3.04$ , and  $2.4 \pm 2.40$  for the 0.65, 2.04, 4.98, and 3.24 mg/L exposure atmospheres, respectively) [2399]. The rats were observed throughout the exposure period (clinical signs recorded at the end of chamber equilibration period and at 0.25, 0.5, 0.75, and 1 h during exposure) and daily (or more frequently as necessary) for an additional 14 d. During the exposure, the rats exhibited exaggerated respiratory movements. During the post-exposure observation period, clinical signs included death (at the two highest concentration exposures only), exaggerated respiratory movements, noisy respiration, lethargy, secretions from the eyes, brown staining around the snout and jaws, and poorly groomed appearance. The lethality data are summarized in Table 93.

**Table 93:** Lethality in rats following 1-h nose-only exposures to 64% hydrazine aerosol.

| Exposure group, mg/L | Males | Females | Total |
|----------------------|-------|---------|-------|
| Control              | 0/5   | 0/5     | 0/10  |
| 0.65                 | 0/5   | 0/5     | 0/10  |
| 2.04                 | 0/5   | 0/5     | 0/10  |
| 4.98                 | 2/5   | 4/5     | 6/10  |
| 3.24                 | 1/5   | 3/5     | 4/10  |

Note: Except for one female in the 3.24 mg/L exposure group that died 3 d after exposure, all deaths occurred overnight following the exposure; there was a 14-d post-exposure observation period.

Data source: [2399]

Using a log probit method, LC<sub>50</sub> values for the 64% hydrazine atmosphere were estimated as 9.0, 5.3, and 6.5 mg/L, respectively, for males, females, and sexes combined (equivalent to 9000, 5300, and 6500 mg/m<sup>3</sup>). Based upon hydrazine content of the hydrazine hydrate solution alone, these respective estimates were 5.8, 3.4, and 4.2 mg/L

(equivalent to 5800, 3400, and 4200 mg/m<sup>3</sup>). Recovery from signs of exposure was observed on day 2 for the 0.65-mg/L groups, and on days 3 and 4 for the 2.04-mg/L groups. For some rats in the higher-exposure groups, exaggerated respiratory movements were observed throughout the post-exposure observation period. Malondialdehyde formation in lung and liver tissue of rats increased following 2-h exposures to hydrazine vapors at different concentrations [2400].

The toxicokinetics of hydrazine, MMH, and UDMH in rabbits during and following inhalation exposure were investigated by administering hydrazine, MMH, or UDMH to different groups of rabbits through *iv* injection and inhalation in different experiments [2401]. Blood, urine, and expired air samples were collected at regular intervals. Concentrations of N<sub>2</sub>H<sub>4</sub> in the samples were determined using colorimetric methods. From these data, the absorption kinetics of N<sub>2</sub>H<sub>4</sub> through respiratory system in rabbits were analyzed, and toxicokinetics parameters were derived. The exhalation rates of N<sub>2</sub>H<sub>4</sub> vapor in respiratory system were as high as 95%, which were not affected by the vapor concentration and ventilation volume. The N<sub>2</sub>H<sub>4</sub> left in the respiratory system could be rapidly and totally absorbed into the circulation system. The half-life of distribution and apparent distribution volume for N<sub>2</sub>H<sub>4</sub>, MMH, and UDMH in rabbits after intravenous injection were calculated to be 0.019–0.048 h and 1.32–1.48 L/kg, respectively. The half-life of elimination after all routes of administration were calculated to be 1.49–2.30 h for N<sub>2</sub>H<sub>4</sub>. The amount of N<sub>2</sub>H<sub>4</sub> excreted in urine was less than 50% of the total elimination. The absorption of N<sub>2</sub>H<sub>4</sub> through respiratory system in rabbits was nearly complete with an apparent zero-order rate. The distribution of the hydrazines in whole body was very quick. There are other elimination pathways of N<sub>2</sub>H<sub>4</sub> other than through the kidney. See also [2402].

Pulmonary toxicity in rats induced by a ternary hydrazine/HN/H<sub>2</sub>O propellant blend called DT-III, whose main component is hydrazine, was studied by intratracheal intubating 0, 5.5, 13.7, 27.5 mg/kg (based on hydrazine content in DT-III), respectively [2403]. Following exposure to DT-III by instillation once a day for 14 d, the rats were sacrificed, and the histopathology, oxidative damage, inflammatory factors, and DNA damage of lung tissue were examined. Results showed that DT-III can cause pulmonary inflammation and oxidative damage. With an increase of DT-III concentrations, the levels of TNF- $\alpha$  and IL-6 in lung tissue homogenate increased gradually. DT-III may induce DNA damage in pulmonary cells.

#### 9.6.1.2 Long-Term (Chronic) Hydrazine Inhalation Studies

In one of the first comprehensive long-term inhalation toxicity studies of hydrazine vapor at the Army Chemical Center, dogs and rats were exposed 6 h daily, 5 d/week at an average concentration of 5 ppm for six consecutive months [2397]. The dogs lost appetite intermittently during exposure. There was some weight loss and fatigue. Recovery could be noted after weekends when exposure was suspended. No deaths were noted in either dogs or rats. However, when the concentration was increased to 14 ppm, 2 out of 4 dogs, 23 out of 30 rats, 15 out of 20 mice, and 8 out of 10 guinea pigs

died during a 6-month test. In rats, an  $LC_{50}$  was determined to be 225 ppm after 4.5 d, 53 ppm after 8.6 d, 20 ppm after 23.5 d, and 14 ppm after 27 d of continuous exposure.

Following the early Army tests, series of long-term inhalation tests spanning several decades were sponsored by the Air Force Medical Research Laboratory and mostly conducted at the Toxic Hazards Research Unit (THRU) of the University of California at Irvine and Mantech Environmental Technology in Dayton, OH. The reports contain a large amount of data on the inhalation toxicity of hydrazines ( $N_2H_4$ , MMH, and UDMH, in addition to the toxicity of Otto Fuel II, diesel, and jet fuels and other chemicals in the military inventory) [2404–2416]. Not all of these reports may deal with hydrazine.

Six-month hydrazine inhalation exposures of mice, rats, dogs, and monkeys were carried out at 5 and 1 ppm intermittent (industrial type) exposure and 1.0 and 0.2 ppm continuous (space chamber) exposure [2417, 2418]. The results (hepatotoxicity in mice, weight loss, and anemia in dogs) indicated that the recommended TLV at that time (1973) was not a safe limit. A group of mice was kept for 1 year following the exposure. The increased frequency of occurrence of alveolargenic carcinomas was a first warning of potential oncogenic problems associated with chronic inhalation exposures to hydrazine.

Serious concern about the safety of previously established TLV limits for hydrazine arose in 1964 when it was found for the first time that continuous 90-d exposure of animals to hydrazine vapor at the then valid TLV (1 ppm) was lethal to 2 out of 10 monkeys, 48 out of 50 rats, and 98 out of 100 mice [2419]. Although a typical TLV load would be only 8 h/d and 40 h/week, this test demonstrated that there was not sufficient margin for safety if this concentration was applied around the clock lifelong. It took more than 10 years and additional testing before the TLV for hydrazine was lowered to 0.1 ppm. Another 10 years and a series of additional tests [2412, 2420, 2421] later, the TLV was eventually lowered further by another order of magnitude to 0.01 ppm.

In a more thorough chronic toxicity inhalation study with hydrazine vapors in air for 1-year exposures, mice, rats, hamsters, and dogs were exposed to concentrations of 0.05, 0.25, 1.0, and 5.0 ppm for 1 year [2394]. Rats were held and observed for 18 months post-exposure, mice 15 months, hamsters 12 months, and dogs 38 months. Male and female rats exhibited dose-dependent incidences of benign nasal adenomatous polyps and smaller numbers of malignant nasal epithelial tumors. Nasal tumors were often associated with chronic irritation and were most frequent in male rats. Hamsters exposed to  $\geq 0.25$  ppm showed pathologic changes indicating degenerative diseases, possibly amyloidosis. At the 5-ppm level, hamsters developed a 10% incidence of benign nasal polyps compared to 0.5% in controls. Also, small numbers of colon neoplasms and thyroid parafollicular cell adenomas were found in hamsters, but only at the highest concentration tested (5 ppm). Lung adenomas appeared to be marginally increased in mice exposed to 1 ppm hydrazine, the highest concentration tested in this species. Only hamsters suffered significant mortality during the exposure phase of the study,

but a mortality of 19% alone in the control group does not speak highly for the health of any of the animals tested. All groups of hamsters lost weight beginning at 12 months. While all these alarming observations were made in rodents, none of the effects could be observed in dogs at any of the concentrations tested, even with the much longer observation periods. Only one dog was diagnosed with liver problems, and pathological examination showed diffuse clusters of swollen hepatocytes. It appears that the nasal tract in rodents is much more sensitive because rodents in their natural habitat spend a large amount of time in the dark, sniffing rather than seeing their food. Under these conditions, the nasal tract is much more sensitive and susceptible to irritation than in non-rodent mammals. Several studies demonstrated that of all tissues tested, the nasal respiratory epithelia of rats and hamsters are extraordinarily sensitive to the tumorigenic action of hydrazine following long-term inhalation [2422]. This is similar to the action of formaldehyde, where also very poor correlation was found between rodent statistics and data obtained in other mammals.

### 9.6.2 Acute Non-Inhalation Toxicity of Hydrazine

Early studies of acute hydrazine toxicity were performed where hydrazine was introduced into the body of test animals by means other than inhalation or skin absorption [2423–2425]. The hydrazine was administered by intratracheal intubation, *iv* injection, *ip* injection, *sc* injection, or orally *po* with or without the use of a stomach tube, which is a more reproducible method than by inhalation or percutaneous absorption. In all cases hydrazine itself was more toxic than any of the methylhydrazines. This comparison is based on a weight basis (milligrams of toxicant administered per kilogram of body weight of animal). Under ordinary conditions of hydrazine usage, the primary concern should be respiratory toxicity, on which basis hydrazine is less hazardous because of its lower volatility. The experiments may not all have administered free hydrazines in solution. In many instances, the free bases were neutralized to pH 7 and dissolved in isotonic saline, in particular for *ip* or *iv* administration [2363, 2384, 2424, 2426–2430]. Repeated administration of subacute concentrations ( $<LD_{10}$ ) of hydrazinium sulfate to mice or rats decreased body weight but had no effect on blood indices. Hydrazinium sulfate increased the sensitivity of the animals to the toxic effects of ethanol or barbiturates.

Prior to 1963, little was known about the mechanism of toxic action of hydrazine. The possibility of interference with  $\gamma$ -aminobutyric acid formation and vitamin B<sub>6</sub>-dependent enzymes was just beginning to emerge. A better understanding of the mechanism has been gained only during the past 50 years. Descriptions of the symptoms of acute poisoning of rats by hydrazines suggested that hydrazine itself acts in a way different from MMH or UDMH [2384].

In a study on the acute toxicity of N<sub>2</sub>H<sub>4</sub>, MMH, UDMH, and SDMH administered (after buffering to pH 7) *ip* to mice, it was noted that the average time to first response with hydrazine was 16 min., UDMH 104 min., MMH 129 min., and SDMH 48–72 h [2363].

Additional animal exposure tests were done with guinea pigs by *iv* injection [2431], rats *po* with their drinking water [2432, 2433], rhesus monkeys by *ip* [2434, 2435], and rats *po* [2436].

### 9.6.3 Nervous System Effects of Hydrazine

The mechanism by which hydrazine acts on the nervous system is not yet completely understood. It is most likely closely related with blood effects and the ability of the blood to provide nerve and brain cells with enough oxygen [2437]. Laboratory studies of nervous system, brain, and cardiac effects of hydrazine are described in [22]. A boiler operator/water treatment technician in the steam plant of a hospital was exposed to hydrazine hydrate vapors for several years while transferring hydrazine solutions from drums into open buckets, from which it was dumped into the boiler feedwater metering tank [2438]. His mental state and attention span degenerated drastically, and he finally was referred for psychological testing. After quitting the boiler job and avoiding hydrazine exposures, he remained under observation for 5 years while undergoing a very slow, only partial recovery of mental capacity.

### 9.6.4 Skin Effects of Hydrazine

Most hydrazines are water soluble and can penetrate the skin barrier. They will also often form chemical bonds to carbonyl and acid groups in the skin material.

#### 9.6.4.1 Animal Studies of Skin Permeation and Absorption of Hydrazine

Hydrazine itself is a stronger skin irritant than any of the methylhydrazines. Skin exposure tests with dogs showed that hydrazine is absorbed through the skin at high rates [2439]. With a dose of 12mg/kg of hydrazine applied to the skin of rabbits (covered with a fiberglass screen and stainless-steel screen to minimize evaporation losses), 86% of all hydrazine applied was absorbed into the bloodstream [2440]. In similar tests with H-70, a 70% N<sub>2</sub>H<sub>4</sub>/30% H<sub>2</sub>O EPU fuel blend, only 55% of all the hydrazine was absorbed. The extent of percutaneous hydrazine absorption in the rabbit appears to be greater than in the dog. It is difficult to extrapolate from these results to human skin. The dermal LD<sub>50</sub> of hydrazine for the rabbit is 91 mg/kg, compared to 20 mg/kg by *iv* injection. The second part of this study exposed rabbits to hydrazine or H-70 for only 2, 6, or 12 min, simulating an accidental splash in a propellant handling situation, where corrective action is taken almost immediately [2333]. The exposure was terminated by rinsing with a dilute hydrochloric acid solution and then with water. For these short exposures, serum concentration of hydrazine peaked 30 to 60 min after the start of the experiment. The third part of the investigation used very dilute solutions of either 15% or 2% hydrazine. There was no damage to the epidermis from the dilute solutions, but permeation through the skin was just as fast as with the more concentrated solutions.

Sixty percent of all hydrazine absorbed at doses of 17.4 and 41.7 mg/kg through the skin of rabbits showed up in the blood within a very short time [2441]. The elimination from the blood occurred with half-life times from 1.49 to 3.8 h. Renal clearance was 37 to 47% of the total body clearance, so there must be other clearance or destruction pathways. In another series of tests, when applied directly to the skin of rabbits, hydrazine caused corrosive skin disintegration [2430].

In an effort to establish a maximum allowable hydrazine in air concentration for propellant handlers wearing only a fresh air mask instead of a SCAPE suit, an exposure chamber was designed in which the shaved skin of six rats was exposed to hydrazine vapor, but the rats were breathing fresh air through a mask [718, 719]. Rats were trained to wear a face mask prior to the exposure experiment. A cannula was implanted into the animals' jugular vein prior to the experiment, through which blood samples could be withdrawn from the outside of the exposure chamber. Parameters for a two-compartment pharmacokinetic model were determined from an *iv* exposure. A two-compartment computer model was used to calculate how much hydrazine was present in each of the two compartments and how much was eliminated. Hydrazine vapor concentrations in the chamber were set at 100 or 500 ppm, which is substantially higher than the TLV. Following a 2-h exposure at 500 ppm, the  $N_2H_4$  concentration in blood peaked at 0.5  $\mu\text{g/mL}$ . The results indicated that hydrazine vapor has very low permeability through skin (0.00006 cm/h), a value like that of water vapor, and much lower than that of lipophilic organic vapors. Exposure limits recommended for special skin-only conditions are summarized in Section 9.11.7. Most inhalation exposure limits are established for simultaneous inhalation and whole-body exposure. Calculations showed that the vapor concentration during a skin-only exposure would have to be at least 200 times higher than that during inhalation to cause the same level of poisoning. In the 1980s when the inhalation TLV for hydrazine was still 0.1 ppm and TLV for UDMH was 0.5 ppm, the equivalent skin absorption TLV concentrations were calculated as 48 ppm for hydrazine and 32 ppm for UDMH, assuming that propellant-handling personnel wears only fresh air masks and face shield, apron, gloves, and boots for protection. This would allow them much better mobility and communication than the bulky SCAPE suits. The skin-only limits for UDMH are lower because UDMH was shown to have a higher skin permeation rate than hydrazine.

#### 9.6.4.2 Adverse Skin Reactions to Hydrazine Exposure in Humans

Several cases of skin rashes caused by hydrazine solutions and hydrazinium salts have been reported in the literature [2442]. The investigators of most of these cases identified the cause by patch tests, a common practice in trying to identify the cause of skin allergies. Two cases of hydrazine hydrate dermatitis without systemic intoxication have been reported [2443]. One patient developed small vesicles on the palm and between the fingers within 1 d following exposure. The patient stated that this was the fourth time he had developed dermatitis after using hydrazine hydrate. During

recovery, he unwittingly came into contact with hydrazine again. Within 7 h, his fingers were irritated, and the rash reappeared. Another patient had repeated episodes of rash and blisters of the fingers. Both patients had been in contact with hydrazine in irregular intervals for about 5 months before developing a skin rash. A 1.5% alcoholic solution of picryl chloride was recommended as a reagent for hydrazine. With this reagent, hydrazine could still be detected in the skin of workers 1 d after the exposure despite normal washing in between. The persistence of hydrazine in the skin is surprising. Apparently, there are no readily reducible compounds in the epidermis that could react with hydrazine. Five cases of allergic skin reactions attributed to hydrazinium sulfate have been reported [2444]. Although the main product of the factory where the five were employed was hydrazinium sulfate, it must be assumed that hydrazine hydrate vapors contributed to the adverse reactions, in particular in the case of the fifth patient, who only walked through the factory on his way to and from his work station. The skin eczema appeared within 2–5 months after the individuals started working in the area. Patch tests with 2% hydrazinium sulfate solutions were positive in most patients. Many of them changed the place of employment and did not suffer from any other skin allergies thereafter. However, 13 more persons working in the same area and so far not complaining of skin afflictions did not react to a patch test with 2% hydrazinium sulfate solution.

Several adverse skin reactions were reported in workers who were exposed to hydrazine hydrate vapor in power plants during boiler feedwater treatment [2445, 2446]. A characteristic feature in hydrazine allergy seems to be cross-sensitization to hydrazine derivatives, especially drugs such as isoniazid or hydralazine. One report described two cases of contact dermatitis caused by hydrazine hydrate [2447]. One marine engineer with no previous skin complaints developed dermatitis of his hands within several months after being assigned to hydrazine hydrate (24%  $N_2H_4$ ) duty. After 4 months of continuous vesicular eruptions on his hands, he resigned and sought different employment. The eruptions cleared within a few weeks. Two years after first working with hydrazine hydrate, he returned to duty on the ship and resumed the handling of hydrazine. Almost immediately he developed a vesicular dermatitis and had to be discharged from the ship. The second fast reaction indicated that a latent sensitization persisted throughout his absence from the ship. A second case was very similar, also involving a marine engineer, and hydrazine was identified by patch tests as a likely cause. The patch test remained positive for several days. There are numerous other reported cases of dermatitis caused by hydrazine exposure at the workplace [2448].

A 22-year-old, active-duty, USAF, senior airperson was seen because of a 1-year history of a slowly enlarging mass on the volar aspect of her left thumb metacarpal-phalangeal joint region [2449]. The patient had worked refueling tactical jet aircraft for the past 4 years. Her duties included refueling F-16 aircraft with hydrazine fuels. She always wore her required personal protective equipment, which included a respirator, coveralls, and gauntlet gloves. She recalled four instances that hydrazine fuel spilled

over the top of her gloves, contaminating her left hand each time. Each time, she followed the prescribed decontamination routine. The patient underwent two operations, with the biopsy of the first tissue removed showing a distinct nodular arrangement of tumor cells. The second operation removed residual tumor cells and replaced the tissue with a skin graft.

There was the case of a 68-year-old man with multiple basal cell carcinomas covering his arms and face after having worked in a steam power plant with extensive exposure to hydrazine hydrate for a period of over 10 years [2450]. A German documentation of MAK values gave a summary of dermatology problems, skin sensitization, and allergies with hydrazine and hydrazinium salts [2451].

### 9.6.5 Eye Effects of Hydrazine Splashes

Ocular toxicity studies of hydrazine and methylhydrazines showed that anhydrous hydrazine splashed on eyes of animals caused permanent corneal damage, whereas methylhydrazines showed only transient effects for 2–7 d [2430].

## 9.7 Carcinogenic Effects of Hydrazine

Several hydrazines have been shown to be carcinogenic in animal tests. As part of the overall effort to understand the conditions leading to the development of cancer, and in order to find a cure of this very complex disease, the carcinogenic actions of hydrazines have been thoroughly studied. The carcinogenic action is most pronounced with SDMH and UDMH and its oxidation products. Though SDMH can induce cancer in a reproducible and predictable way, this is not the case with hydrazine  $N_2H_4$  itself. Many tests have been done with hydrazinium salts, but they may lead to different results. Hydrazine or hydrazine hydrate that is ingested would be quickly converted to hydrazinium chloride by stomach acid. Besides UDMH, autoxidation products such as dimethylnitrosamine (*N*-nitrosodimethylamine, NDMA) are listed among the most potent carcinogens known. NDMA used to be produced as an intermediate in the manufacture of UDMH. Because of increased concern about NDMA carcinogenicity, several UDMH production facilities in the United States were shut down since the plants could not be modified to assure zero emissions of NDMA. It is not known which UDMH production process has been used or is now used in Russia and the other former states of the USSR as well as in China and North Korea.

This section of the book on the carcinogenic effects of hydrazine is an abbreviated and updated version of chapters offered in previous books on hydrazine [2452]. It would require too much space to deal with that subject again here in detail. Readers who need more detailed information are referred to the aforementioned source.

A question that has been asked frequently but has not been answered conclusively is the correlation between animal test results and carcinogenic risks to humans. Hy-

drazines have been designated as “suspect human carcinogens.” But if one follows the several decades of wavering on-again, off-again designations for such a commonly used household item as saccharin sweetener, one really wonders how accurate such designations are.

The existence of many designated rodent carcinogens for which at least one epidemiological study found no evidence of human carcinogenicity has thrown doubt on the validity and poor predictivity of rodent bioassays [2453]. In a review of correlations between rodent bioassays and human epidemiological studies, for 18 of the 22 chemicals examined, the human evidence was consistent with predictions based on the rodent bioassay results. Hydrazine was included in the group of 18, but it seems that the correlation was misinterpreted. The number of deaths found to be attributable to exposure in the cited epidemiological study of hydrazine was 2 deaths observed vs. 1.25 expected, which is not a significant difference due to the small number of incidents.

Epidemiological and mortality studies on chemical industry workers who were exposed to hydrazine vapors for up to several decades at their workplace have not revealed an increased incidence of cancers [2454–2457] (Section 9.10).

A good way to stay informed on the latest developments on carcinogens and government regulations affecting potentially hazardous chemicals is to tap into the web sites of some toxicology research organizations, such as [2458–2461]. In 1997 the US Department of Health and Human Services published new criteria for determining whether substances can be listed as “reasonably anticipated to be a human carcinogen.” The new criteria allowed the determination to be made not solely on rodent research data, but on a broader scientific base that includes the known chemical structure of the substance and its effects at the cellular level. In the Biennial Report on Carcinogens, the National Toxicology Program (NTP) lists substances “known to be human carcinogens” as well as substances “reasonably anticipated to be human carcinogens.” Since 1981, when the report was first published, the “reasonably anticipated” list has been based on experiments in which rats and mice have been exposed to the substances in question, as well as limited human data. The new criteria will allow the listing to be based on broader and more sophisticated criteria. The new criteria were developed through a collaborative process involving cancer scientists as well as consumer and industry representatives.

In addition to the new scientific criteria, the NTP is also creating a new process that will accommodate continuing advances in the science and that will provide a more structured approach to listing and de-listing of substances. Under the new criteria, even though there may not be available direct evidence that a substance causes cancer in humans, or in traditional bioassays using rats and mice, the substance could still be listed as “reasonably anticipated to cause cancer in humans” if there is convincing information that it works in living cells in a similar manner as other known human carcinogens. Conversely, if a traditional 2-year study shows a substance to cause cancer in laboratory rodents, the substance would not be listed

if there were compelling data showing that the action or mechanism by which the cancer in laboratory animals occurred did not exist in humans. Most of the 180 substances listed in the Biennial Report, including hydrazine, hydrazinium(2+) sulfate, and UDMH, are listed as “reasonably anticipated” to be a human carcinogen and are listed based on studies performed in laboratory animals and linked to an increased incidence of malignant tumors in two or more species, or in two or more studies, or when there are particularly unusual cancers that do not normally occur in the animals studied. The criteria have been revised to state:

Conclusions regarding carcinogenicity in humans or experimental animals are based on scientific judgment with consideration given to all relevant information. Relevant information includes, but is not limited to, dose response, route of exposure, chemical structure, metabolism, pharmacokinetics, sensitive sub-populations, genetic effects or other data relating to mechanism of action, or factors that may be unique to a given substance. For example, there may be substances for which there is evidence of carcinogenicity in laboratory animals, but there are compelling data indicating that the agent acts through mechanisms which do not operate in humans and would, therefore, not reasonably be anticipated to cause cancer in humans. *Quoted from NTP Documentation*

The original criteria for listing a substance as a known human carcinogen remain unchanged: that “there is sufficient evidence of carcinogenicity from studies in humans which indicates a causal relationship between exposure to the agent substance or mixture and human cancer.” With regard to hydrazine and hydrazinium(2+) sulfate, the NTP listed both under the category “reasonably anticipated to be carcinogen” and stated (with our reference numbers substituted):

There is sufficient evidence for the carcinogenicity of hydrazine and hydrazine sulfate in experimental animals. When administered orally, hydrazine induced pulmonary adenomas and adenocarcinomas in mice (IARC). Intraperitoneal injection of hydrazine induced reticulum cell sarcomas of the mediastinum and myeloid leukemias in mice. When administered by inhalation, hydrazine induced alveolarogenic carcinomas, and lymphosarcomas of the spleen, in female mice [2418]. When administered orally, hydrazine sulfate induced pulmonary adenomas and adenocarcinomas, hepatomas, and hepatocarcinomas in mice of both sexes. When administered by stomach tube, hydrazine sulfate induced lung adenomas and adenocarcinomas in rats of both sexes and hepatic cell carcinomas and spindle cell sarcomas in male rats [2462]. There is inadequate evidence for the carcinogenicity of hydrazine and hydrazine sulfate in humans [2463]. *Quoted from NTP Documentation*

On the other hand, the 7<sup>th</sup> *Annual NTP Report on Carcinogens* (1997) listed no hydrazines as known carcinogens, but it did include 24 other chemicals like benzene and asbestos. Another valuable on-line source of information on carcinogenic potency of chemicals in comparison to that of hydrazines is the Carcinogenic Potency Database (CPDB) [2464]. The Carcinogenic Potency Database reports analyses of animal cancer tests on 1547 chemicals. This is a widely used resource on the results of chronic, long-term animal cancer tests. It provides a single, standardized, and easily

accessible database that includes enough information on each experiment to permit investigations into many research areas of carcinogenesis. Both qualitative and quantitative information on positive and negative experiments are given, including bioassays from the National Cancer Institute/National Toxicology Program (NCI/NTP) and results from the general literature that meet a set of inclusion criteria. As of 1997, analyses of 5152 experiments on 1298 chemicals were presented. For each experiment, information is included on the species, strain, and sex of test animal; features of experimental protocol such as route of administration, duration of dosing, dose level(s) in mg/kg body weight/d, and duration of experiment; histopathology and tumor incidence; carcinogenic potency ( $TD_{50}$ ) and its statistical significance; shape of the dose-response curve; author's opinion as to carcinogenicity; and literature citation. There is a printed version of the *Carcinogenic Potency Database* and user's guide which contains an index with chemicals listed by CAS registry number and allows cross referencing between the carcinogenicity and genotoxicity databases, making data easy to find [2465].

The US EPA has designated hydrazine as a probable human carcinogen, classified as weight-of-evidence Group B2 under the EPA Guidelines for Carcinogen Risk Assessment [2466]. Evidence on potential carcinogenicity from animal studies is "sufficient," and the evidence from human studies is "inadequate." The potency factor for hydrazine was estimated to be  $107 \text{ mg kg}^{-1} \text{ day}^{-1}$ , placing it in potency group 1 according to the CAG's methodology for evaluating potential carcinogens. Combining the weight-of-evidence group and the potency group, hydrazine was assigned a "HIGH" hazard ranking for the purposes of Reportable Quantity adjustment [2467].

The US government and several government agencies, including the armed services, in particular the USAF, have struggled with the mounting indications of animal carcinogenicity and attempted to establish policies under which the continued use of hydrazine propellants had to be justified and all necessary precautions taken to prevent exposure of propellant-handling personnel to propellant vapors [2301]. One of the first precautions was to lower the exposure limits for inhalation of hydrazines, but it was not possible to quantify the cost and benefits, i.e., the cost:benefit ratio of such an action (Section 9.11). At one time [2468] it was considered safe enough to lower the TLV from 1.0 to 0.1 ppm to protect the working population from hydrazine-induced cancer, but a few years later the TLV was lowered by another order of magnitude for an extra measure of safety. The working populations who lived through the several decades when the TLV was still 1 or 0.1 ppm showed no adverse effects that were clearly induced by exposure to only one chemical.

Special caution is recommended in extrapolating from animal data to toxicity and tumorigenesis in humans. The animal data are often inconsistent. Researchers sometimes do not always stick to the correct protocol for animal exposure and twist the data to yield the results they were hoping for. Depending on the mode of administration and the type or strain of test animal used, hydrazine itself produced a high rate of tumors in some animals. However, in other animals under otherwise identical

conditions, no tumors were found at all. Compilations of the carcinogenic risk of hydrazine chemicals to humans were published repeatedly by the International Agency for Research on Cancer (IARC) [2462]. The IARC *Monograph on the Evaluation of the Carcinogenic Risk of Chemicals to Humans* was updated in a supplement in 1987 and again updated in 1999 [2469]. In addition, interpretations of negative epidemiological evidence for the carcinogenicity of hydrazine have been discussed in another special scientific report published by IARC in 1985 [2455, 2470]. Hydrazine was considered by the IARC Monographs Working Group in 1973, 1987, and 1998 (published by IARC in 1974, 1987, 1999).

In February 2016, 24 experts from 8 countries met at the IARC in Lyon, France, to assess the carcinogenicity of 7 industrial chemicals [2471]. The experts concluded that there was limited evidence in humans for the carcinogenicity of hydrazine, that a positive association has been observed between exposure to hydrazine and cancer of the lung, and that there is sufficient evidence in experimental animals for the carcinogenicity of hydrazine. IARC classifies chemicals suspected of causing cancers in humans in five categories:

- Group 1: The agent is carcinogenic to humans.
- Group 2A: The agent is probably carcinogenic to humans.
- Group 2B: The agent is possibly carcinogenic to humans.
- Group 3: The agent is not classifiable as to its carcinogenicity to humans.
- Group 4: The agent is probably not carcinogenic to humans.

Hydrazine was evaluated previously as **possibly** carcinogenic to humans (Group 2B), but in its most recent 2018 edition, IARC classified hydrazine in Group 2A: “*The agent is **probably** carcinogenic to humans*” [2472]. This is a substantial change from their previous assessment of the risks associated with hydrazine exposure.

In reviewing dozens of animal studies, it becomes clear that a carcinogenic effect can only be demonstrated for hydrazine when it is administered for practically the whole life of the animals in toxic doses that do not reduce the life span very much. In many instances only the unambiguously toxic concentration after the longest possible period produced a weak carcinogenic effect. These lifelong conditions do not apply to human occupational exposure.

In laboratory test animals, hydrazines and related compounds may cause cancers of the colon [2473], lung [2474–2477], skin [2450], or nasal cavity [2468]. Even naturally occurring hydrazine compounds can induce colon cancer [2478]. To better understand chemically induced cancer in test animals and cancer of unknown causes in humans, it is of interest to compare the actions of known site-specific carcinogens on identical parts of the body (i.e., the colon) of humans and test animals.

The use of rodent whole-body exposure data to set TLVs for human exposure at the workplace has been criticized, but there are currently no other generally accepted methods to determine safety data. It has been argued that rodents often lick themselves and that they absorb more hydrazine by ingestion than inhalation. Their food

sits in the same atmosphere they are inhaling, and the food and drinking water become saturated with hydrazine. This would not be the case for humans in an occupational setting.

The use of rodents for hydrazine inhalation tests has been criticized, arguing that rodents spend most of their natural life (not talking about pampered test animals in a laboratory cage) in dark burrows, where they depend on the sense of smell to sniff their way around. The sense of smell is much more developed, the olfactory organs more sophisticated and more vital for rodents than they are for humans. Consequently, the nose (where some of the hydrazine-induced adenocarcinoma have developed) is a location of high cell turnover in rodents and more susceptible to chemical insults. The same argument arose about the use of formaldehyde toxicity data from animal tests. These data were needed after it was found that most plywood used in domestic construction (mostly mobile homes) emitted formaldehyde for a long time after it was laminated together.

## 9.8 Mutagenic and Teratogenic Effects of Hydrazine

A detailed summary of the mutagenic effects of hydrazine and methylhydrazines was provided in [2479], which has not yet been updated. Hydrazine and hydrazine derivatives have been shown to have mutagenic effects in plant and insect chromosomes and in bacteria [2480]. Hydrazine was mutagenic in a host-mediated assay [2481]. Hydrazine can cause mutations by reaction with DNA [2482]. In many cases hydrazine and hydrazine derivatives are outright cytotoxic, such that bacteria exposed to these chemicals do not even have a chance to multiply and mutate. Hydrazines may interfere with the metabolism of these bacteria [2099].

The *in vivo* genotoxicity of three hydrazines, SDMH, UDMH, and hydrazine  $N_2H_4$ , was tested in mouse liver, lung, kidney, brain, and bone marrow and in the mucosa of stomach, colon, and bladder [2483]. Hydrazine  $N_2H_4$  at 100 mg/kg yielded DNA damage in the stomach, liver, and lung when given *ip* and in the brain when given *po*. Thus, the administration route is important when evaluating organ-specific genotoxicity in multiple organs. A summary of the teratogenic effects of hydrazine and methylhydrazines appears in [2484], which has not yet been updated.

## 9.9 Hydrazine Use History and Accident History

### 9.9.1 Hydrazine Use History and Use Statistics

It has been estimated that as of 1987, 10528 workers in the US were potentially exposed to hydrazine (hydrate) part-time and 1156 workers were potentially exposed full-time [2465, 2485].

### 9.9.2 Hydrazine Accidental Exposure History

Several cases of accidental human exposure to hydrazine are described in the literature. All accidents were the result of gross neglect of standard safety procedures in handling hazardous chemicals [2353, 2354, 2486–2497]. There were several poisoning accidents in workers in steam power plants where hydrazine hydrate solutions were used for boiler feedwater deoxygenation [2438, 2498, 2499].

## 9.10 Epidemiological and Cohort Studies of Hydrazine Exposure

This section deals with long-term, chronic exposure studies and not with the consequences of occasional accidental exposure episodes. Epidemiological studies in this narrow context of workers in chemical factories and rocket test sites must be viewed against the ubiquitous presence of hydrazine derivatives in the environment, in food (mushrooms), and in pharmaceutical applications. It has been estimated that hundreds of millions of people all over the world are exposed to varying amounts of artificial and naturally occurring hydrazines, even before the space age (yet people continue to live) [2287].

A very detailed epidemiological evaluation of workers exposed to hydrazine (hydrate) has been carried out in Great Britain as a voluntary cooperative project of nine hydrazine hydrate producers [2500]. Five of the nine companies had started manufacturing hydrazine hydrate on dates ranging from 1940 to 1956. One company had records of all 53 men employed in hydrazine hydrate manufacture for more than 10 years between 1940 and 1974 (the date of the study). Another company operated a hydrazine hydrate manufacturing plant between 1945 and 1970 and had records of all 423 people who had worked at the plant during that period. When assembling data from both companies in categories by the level and duration of exposure, only a fraction (64%) of the people involved could be traced and their state of health ascertained. Several had died of natural causes not related to any suspected chemically induced cancer. Of those traced, 18 had died, and 2 of these from cancers. Mortality and frequency of cancers were not different from those of a group of workers of identical age calculated from statistical tables. The observed and expected number of deaths were similar. While the existing data were crude and incomplete, they indicated that these past occupational exposures to hydrazine did not result in any greatly increased risk of cancer.

This 1978 preliminary analysis of men working at a hydrazine plant did not reveal an excess risk of cancer associated with exposure to hydrazine. The follow-up was incomplete, however, and as mortality was not analyzed by cause, a fresh study was conducted using the same cohort. The cohort of 427 men from the larger of the 2 manufacturers was studied further and the results were reported in an IARC scientific publication on the *Interpretation of the Negative Epidemiological Evidence for Carcinogenicity* [2454, 2455]. The facility where the exposures had occurred was located

in the east Midlands of England. It had produced 700 tons of hydrazine in the form of hydrazine hydrate per year during the years from 1945 until 1971 when it was closed. The hydrazine hydrate was processed into derivatives on-site in open vats. This study involved a group of men who had worked at the site for at least 6 months during this period. The subjects were categorized by their severity of exposure, one group associated with the direct manufacture of hydrazine, a second group with incidental presence in the area of hydrazine hydrate production (e.g., pipe fitters, engineers), and a third group with no documented work assignments in the hydrazine hydrate plant. It was possible to trace 406 (95%) of the 427 men. No hydrazine in air measurements had been taken in the factory, but it was common practice to make hydrazine derivatives in open vats in a closed building with no enhanced ventilation to bring in fresh air. In those days, hydrazine hydrate vapor was considered a nuisance, just like ammonia. It is estimated that hydrazine in air concentrations in this part of the plant varied between 1 and 10 ppm with local spikes of 100 ppm. In the cohort of 427 men, as of July 1982, there were 49 deaths (61.47 expected) from all causes, including 5 deaths from lung cancer (6.65 expected). Two of the lung cancer deaths occurred in the group with the heaviest exposure, where only 1.61 were expected. One had worked in the high hazard area for 16 years, the other for only 2 months. None of the deaths involved nasal cancer. Realizing that the total number of exposed workers was statistically small, the preliminary results showed that there was no obvious hazard associated with hydrazine exposure, and continuation of the epidemiological study was highly recommended. The study was continued, and by the end of January 1992, a further 37 deaths had occurred [2456]. Again, the observed mortality for the total cohort was close to that expected for all causes and for lung cancer, cancers of the digestive system, other cancers, and all other causes, irrespective of the level of exposure. Men in the highest-exposure group did not seem to have significantly different mortalities for lung cancer, compared with other men in this study or compared with the population at large. The only category where the number of observed deaths exceeded statistical expectations was the high-exposure category for men with more than 6 months of exposure (3 observed vs. 2.43 expected). Cancers in the digestive system in the low to moderate exposure group was slightly elevated (8 vs. 6.54 expected).

It is fortunate that the study was continued, covering a 50-year period, and by the end of December 2012, 205 deaths had occurred [2457]. For men in the highest exposure category with greater than 2 years of exposure and after more than 10 years since the first exposure, the relative risks compared with national rates were 0.85 (95% confidence index (CI): 0.18–2.48) for lung cancer, 0.61 (95% CI: 0.07–2.21) for cancers of the digestive system, and 0.44 (95% CI: 0.05–1.57) for other cancers. The only categories in which the number of observed deaths exceeded expected deaths (but not significantly) were lung cancer in men in the high exposure category for 6 months or more (6 observed vs. 4.55 expected), cancers of the digestive system in men in the moderate or low exposure category (20 observed vs. 17.21 expected), and ischemic heart disease in men in the high exposure category for 6 months or more (16 observed vs. 14.56 ex-

pected). Half of the six deaths from lung cancer in men in the high exposure category were in men exposed in that category for less than 2 years. Two deaths from cancer of the digestive system occurred in men with exposure in the high exposure category compared to 3.27 expected. After 50 years of follow-up, the results provided no evidence of an increased risk of death from lung cancer or death from any other cause as a result of hydrazine vapor exposure. The strengths of this study are that it constitutes one of very few datasets available on exposure to hydrazine, and there is now 50 years of follow-up. We hope similar epidemiological studies will be carried out on hydrazine (hydrate) workers at other production and usage facilities.

A similar study in France of 140 men working at a plant producing hydrazine hydrate since 1962 reached similar conclusions (personal communication Cordier to Morris 1995). No significant excess in incidence of cancer was observed in the cohort of workers in comparison to the statistical numbers expected from local cancer incidence. However, an excess of digestive cancers was found in the low exposure group. No excess of respiratory cancers was observed in the French study.

A mortality study submitted in January 1979 on workers who had worked for at least 3 months in a hydrazine hydrate plant during the years between 1953 and 1978 showed an increased incidence of myocardial infarction (death and non-death). There were five cases of myocardial infarction vs. 1.2 cases expected statistically. The average duration of hydrazine work employment for the five men was 16 years. This higher incidence of heart attacks may be simply stress related and may not have been chemically induced. Additional data gathered during the observation period 1978–1985 revealed no increased myocardial infarction incidence among workers [2501]. It was concluded that the experienced cluster of incidents was a chance occurrence and did not represent a direct health hazard. Otherwise, the hydrazine exposed workers were no different from any of the other groups.

A Danish Air Force study involved medical surveillance on personnel working with EPU maintenance in F-16 fighters. Since the introduction of the F-16 system in Denmark, 41 male technicians had been routinely examined due to these regulations, and personnel potentially exposed to H-70 during three leakage incidents were examined, but no lasting effects were noted [2492].

One study suggested that workers most likely exposed to rocket fuel hydrazines and other chemicals at the Rocketdyne Santa Susana Field Laboratory in Simi Valley, CA, were more likely to have died of lung cancer and several other types of cancer than were co-workers not exposed to the chemicals [2502, 2503]. The purpose of the study was to estimate the effects of occupational exposures to selected chemicals on cancer mortality among nuclear and aerospace workers who were employed at Rocketdyne/Atomics International between 1950 and 1993. There was an excessive number of cancer deaths among workers in the high-exposure hydrazine group. The study, which examined 6107 men first employed at the Rocketdyne plant before 1980, found that workers presumed to have a high exposure to hydrazine or other chemicals in the workplace died from lung cancers and possibly cancers of the bladder, kidney, and

blood and lymphatic system about twice as often as other Rocketdyne workers who were not exposed to the chemical. One must realize that the workers were exposed at the workplace to many other chemicals in addition to hydrazine, so hydrazine cannot be singled out as the sole cause of the higher incidence of cancer mortality.

All three hydrazines, hydrazine itself, MMH, and UDMH were implicated in an epidemiologic, retrospective study of causes of death among former workers at a large aerospace company in California. The results of this retrospective cohort study suggested that exposure to hydrazine or other chemicals associated with the same jobs at rocket-engine test stands increased the risk of dying from lung cancer and possibly other cancers [2504, 2505]. However, the hydrazine chemicals were just a few of several other chemicals and other adverse conditions these workers might have been exposed to while working in various jobs in the defense and aerospace industries. Any one of these other chemicals could have caused the observed effects and hydrazine(s) cannot be singled out as the sole cause. There were no records of actual workplace concentrations of hazardous vapors in the air that could be correlated with the effects observed in sick people several decades later.

A similar retrospective cohort mortality study of 8372 Rocketdyne workers employed from 1948 to 1999 at the Santa Susana Field Laboratory came to a different conclusion [2506]. Non-significant associations were seen between lung cancer and hydrazines, and stomach cancer and years worked as a test stand mechanic. No trends over exposure categories were statistically significant. It was concluded that work at the rocket engine test facility or as a test stand mechanic was not associated with a significant increase in cancer mortality overall or for any specific cancer.

A statistical survey of frequency of prostate cancer in workers who were employed between 1950 and 1992 at a nuclear energy and rocket engine-testing facility in Southern California and had been exposed to a variety of solvents (including trichloroethylene, a popular degreaser solvent) and propellants (hydrazine) revealed that high levels of trichloroethylene exposure were associated with more frequent cases of prostate cancer among workers in this study population [2507, 2508]. This study was not specific for hydrazine, which was just one of several chemicals and possibly nuclear radiation these workers were possibly exposed to.

Despite the thousands of tons of hydrazine fuels handled by USAF personnel during the past decades, a review of exposure data published in 1976 indicated only six exposures, none of which proved to have significant consequences [2304]. The scarcity of exposure information is no doubt due to the careful approach that the armed forces have applied to the handling of the hydrazine fuels, sometimes involving the use of self-contained breathing apparatus. In a 1978 survey, it was stated that "there are no known cancer cases among hydrazine, MMH, and UDMH propellant manufacturing and handling personnel as of today" [2281–2283].

The F-16 air combat fighter, which entered service in the USAF in 1979, is the first production fighter aircraft to use a monopropellant hydrazine EPU. Although the quantity of hydrazine flown on each aircraft is small in comparison to the quantities

used in expendable launch vehicles, reusable space launchers, space stations, or ballistic missiles, the number of persons potentially exposed to a hydrazine-contaminated environment is large. Every effort was made by the USAF medical staff to provide for adequate protection of service personnel exposed to hydrazine hydrate during servicing of the EPU [705, 2301, 2509, 2510]. Part of this effort was an education and training program for flight-line personnel. For maintenance and repair on the F-16 EPU, a potentially large number of military service personnel and contractors could be exposed to hydrazine vapors in case of spills and violations of safety procedures. The USAF has established guidelines and test protocols to protect its personnel and to assess the toxicity of the chemicals used for power generation and propulsion [2511]. A survey conducted by USAF laboratories on the magnitude of potential hydrazine exposure during EPU maintenance during the development phase identified some deficiencies that were promptly corrected, and engineering changes to system hardware and support equipment were implemented. Although the USAF had considerable experience in the safe handling of hydrazines for space and missile applications, the introduction of H-70 to the flight line presented new and challenging problems to the USAF medical and aircraft maintenance communities. Flight-line servicing of a used EPU involves depressurization of the tank, expelling residual H-70 from the lines through the catalyst bed, and replacing the H-70 tank with quick-disconnect fittings. Hydrazine concentrations measured in the vicinity of maintenance operations ranged from 0.0001 to 0.007 mg/m<sup>3</sup> when calculated as a TWA spread over the 8-h work shift and were well below the TLV [2512]. The approach later taken as a joint effort between the USAF and industrial suppliers emphasized the importance of a closed system concept. Prior to introducing the F-16 to the flight line, an Air Force Occupational Safety & Health Standard 161-13 was developed for hydrazine to provide detailed surveillance. Because the records to be kept on the population at risk of exposure will be very accurate and detailed, further epidemiological studies will have a good database to work from. It was planned that for the first year of the F-16 program, occupational hygiene monitoring would be done on a quarterly basis. As of 1995, approximately 3600 F-16 fighter jets were flying in the armed forces of many countries worldwide. NATO countries that were adding F-16s to their arsenal in the early 1980s have also prepared themselves for the safe handling and disposal of H-70 in case of unexpected events [2513].

Although the concentrations are usually very small, residual hydrazine in the blowdown from steam power plants constitutes a potential hazard to workers and surrounding communities [2514], but in recent times precautions have been taken to remove residual hydrazine from the condensate before it is discharged to surface waters.

A review of chemical industry-wide epidemiological studies in the US and Western Europe selected the Morris 1995 study as one of 181 qualifying studies among 385 studies, and data were abstracted from the 181 studies representing the most recent report for a cohort, or the earlier study of the same cohort that provided relevant data according to stringent selection criteria [2515]. Of these, 156 reported only mor-

tality data, 10 reported only incidence data, and 15 reported both mortality and incidence data. Only 69% of the studies reporting mortality data received “satisfactory” quality scores, and the Morris 1995 study was among them. The Morris et al. 2015 50-year follow-up [2457] would also qualify. Overall, 10% fewer premature deaths were observed than expected.

Workplaces where hydrazine or hydrazine derivatives are handled must be monitored. Airborne concentrations need to be measured and recorded over several work shifts and on non-working days to determine the background contamination without manufacturing and testing activities in progress. In terms of the quantities of hydrazine(s) stored and transferred, the Rocky Mountain Arsenal near Denver, CO, was the leading propellant storage and mixing facility in the US in the 1960s and early 1970s. Unfortunately, it left a not-so-pleasant legacy of environmental contamination that took many years to clean up.

Air sampling during fuel transfer operation was done once in conjunction with the evaluation of respiratory protection (gas mask canisters) for workers at Rocky Mountain Arsenal. Measurements were on the order of 2 ppm hydrazine and 3 ppm or even up to 4.6 ppm UDMH. Air samples were taken in 1976 and 1977 during drum and truck/rail tanker filling operations [2516]. The sampling methods used were sulfuric-acid-coated silica gel tubes and impingers. Air samples were taken both outside and inside gas masks worn by propellant handlers. Outside air samples were typically on the order of 0.2 ppm for hydrazine and UDMH, with peak excursions of 1.66 ppm hydrazine or 1.98 ppm UDMH. Air inside the gas masks was clean. If there was any hydrazine or UDMH, it was close to the detection limit. The TLV in effect at the time was 1 ppm for hydrazine and 0.5 ppm for UDMH, but lowering to 0.1 ppm was imminent. The odor of hydrazine and UDMH was noted when walking past the storage area, outside the general work area proper. NDMA was detected in the air in the vicinity of UDMH storage tanks. Some of the operating procedures had been improved, and necessary repairs were made before the inspection team returned several months later. Shortly before the facility was shut down, air samples were taken and analyzed for NDMA in 1980 while railroad cars and tankers were cleaned and loaded [2517]. NDMA was found in the entire area using two different sorbent tube materials. Since there was no gas mask with proven effectiveness against NDMA, industrial hygiene staff recommended that compressed air respirators should be worn when working in the area. Another inspection 2 years later, after shutdown of operations, found no detectable hydrazine or UDMH in the air (D.L. of  $0.05 \mu\text{g}/\text{m}^3$   $\text{N}_2\text{H}_4$  or  $0.1 \mu\text{g}/\text{m}^3$  UDMH), but persistent NDMA levels of typically  $2 \mu\text{g}/\text{m}^3$  (D.L.  $0.05 \mu\text{g}/\text{m}^3$ ) with excursions of  $20 \mu\text{g}/\text{m}^3$  were noted [2518]. The silica sorbent for hydrazine analysis was replaced with fire brick for the later set of analyses. Air sampling at Rocky Mountain Arsenal Hydrazine Blending Facility continued for several more years while the cleanup was in progress [2519, 2520].

An industrial hygiene study including walk-through industrial hygiene surveys of several industrial and government sites was conducted by a contractor for NIOSH [2521, 2522]. As part of this study, the team assembled tables of job titles

of exposed workers and exposure levels, determined the significance of recurring and non-routine exposures, and assessed the reliability of exposure data gleaned from exposure records provided by the facilities visited. Walk-through and in-depth industrial hygiene surveys were conducted between February 1983 and February 1984 at eight facilities in the US where hydrazines were produced and/or used. The sites visited included three hydrazine and hydrazine-derivative manufacturers, one USAF base, an aircraft manufacturer, and three sites where space propulsion systems were tested. Many boiler operators were contacted, but none agreed to a site visit. Only one provided data gathered in boiler water treatment rooms at nine of its power plants. From the information gathered during the visits, the investigating team concluded that employees and employers were aware of the toxic effects of hydrazine(s) and the need to avoid exposure. The time-weighted averages (TWAs) reported and observed were well below the TLV (0.1 ppm) and recommended NIOSH limits (0.03 ppm) in effect at the time. The number of exposed workers was reported to be small; only a few workers were involved in hydrazine manufacture and the routine use of hydrazine(s) as propellants. Because many of the process plants were relatively new and because not too many years had passed since the introduction of the F-16 EPU, it was considered unlikely that suitable cohorts existed in 1985 for retrospective exposure studies. Only one of the eight facilities selected for walk-through inspection was revisited for more in-depth air sampling: An industrial hygiene survey of Olin's ketazine hydrazine production unit at Lake Charles, LA, was conducted by a contractor for NIOSH [2523]. Worker exposures to hydrazine vapor were determined by pumping air through solid sorbent (sulfuric acid on fire brick) tubes, which were later extracted, and the extract analyzed by PDAB spectrophotometry. Full-shift, time-averaged hydrazine exposure concentrations ranged from less than 0.002 to 0.27 ppm. Generally, concentrations were well below the TLV in effect at the time (0.1 ppm).

Another summary report on human exposure to hydrazine in the workplace lacked actual measurements [2524]. Instead, it relied entirely on measurements taken by other investigators and quotes 53 obsolete references from the literature.

A survey team from the USAF Occupational and Environmental Health Laboratory conducted an analysis of maintenance tasks associated with the F-16 EPU [2525]. This analysis involved the collection of personal and short-period air samples to define airborne exposure to hydrazine during maintenance tasks, such as nitrogen depressurization, catalyst purge, poppet valve replacement, and refilling. Measurements indicated compliance with a time-weighted-average value of 0.1 ppm hydrazine; however, potential peak exposures that ranged as high as 5 to 8 ppm occurred during some tasks. A technician would be unaware of many such exposures, since concentrations below the odor threshold of 3 to 5 ppm give no warning but are at least an order of magnitude above acceptable occupational exposure limits. Data collected during two on-site surveys of F-16 maintenance installations indicated that (prior to imposing stricter controls) hydrazine concentration in the vicinity of a piston tank being in-

stalled or depressurized on the aircraft was 0.03 ppm, and during on-the-ground (off-the-airplane) tank servicing it was 0.03–0.12 ppm, with possible short-time excursions of up to 6 ppm. After imposing stricter controls, the concentrations during piston tank servicing were brought down to below 0.01 ppm, one-tenth of the TLV-TWA in effect in the late 1970s [705, 2525].

Measurements at NASA KSC showed that occupational exposure of technicians to hydrazine and MMH vapors was well within tolerable limits even after the lowering of the TLV from 100 to 10 ppb in 1991 [2526]. Sampling methods were sensitive enough to measure exposure levels at or below the proposed ACGIH TLV of 10 ppb/8 h. The operations monitored included propellant transfer operations, flight hardware processing, and launch vehicle fueling operations that occurred at KSC or the adjacent CCAFS. A similar set of 128 air samples taken and analyzed for hydrazine, MMH, and UDMH at NASA WSTF in 1991 showed that hydrazine or MMH concentration in most work areas was below the proposed TLC of 10 ppb [2527]. The air samples were taken by aspirating air through glass tubes filled with USSS No. 30–60 granular sulfuric acid impregnated fire brick at a rate of 1 L/min for 10 min. The sorbent was then leached with buffer solution in an ultrasonic agitator and the solution analyzed by HPLC with electrochemical detection. Several samples were reported as “none detected,” but unfortunately, the detection limit was not stated (it is assumed to be below 2 ppb). Parallel tests showed the dubious value of conventional Interscan 4186 measurements that did not correlate with the absorption tube readings at all.

A workplace occupational hygiene survey was carried out on 172 male hydrazine-hydrate-exposed workers and 125 male unexposed reference workers at 5 factories in Japan [2528, 2529]. The biological half-lives of hydrazine hydrate after 1 h of exposure were determined in 12 workers, 4 workers in each of 3 NAT2 phenotypes. No hydrazine was detected in either the breathing zones or the urine of the reference workers. The mean hydrazine concentration in the breathing zones, hydrazine, and acetylhydrazine in urine, and the cumulative exposure levels were 0.0109 ppm, 0.8660 micromol/g, and 2.80 ppm-years, respectively. There was no difference and no dose-dependent change in the health examination items between hydrazine-hydrate-exposed and reference workers after adjusting confounding factors, nor in terms of the differences of NAT2 phenotypes. The half-life time of urinary hydrazine and acetylhydrazine on rapid, intermediate, and slow phenotypes was 1.68, 3.01, and 4.46 h, respectively. This information would be useful if a biological exposure index (BEI) for examination of post-work-shift workers could be found.

### 9.11 Established Exposure Limits for Hydrazine

Many different types of exposure limits are in use for establishing safe working and living conditions. There are many variables that must be taken into consideration when setting tolerable limits. This applies to the inhalation of air contaminants as well as

the tolerable concentrations of food additives or pesticides in food. The section here only deals with airborne contaminants, those that are primarily absorbed by inhalation, although some of these may also be absorbed by and permeate through the skin. The margin of safety is required to cover at least the average population (assume a 3 $\sigma$  distribution of resistance to chemical attack). In many cases the tightening of exposure limits comes at a substantial cost of enforcement or implementation of engineering controls. Typically, the guideline maximum limit for a toxic chemical is set at one to two orders of magnitude below levels demonstrated in animal experiments to be without adverse effect. For carcinogens, it is very difficult to demonstrate the no-effect concentration. Some toxicologists suggest that no level of exposure to carcinogens, no matter how small, is without potential for harm. Of course, they would like to outlaw cosmic radiation, as well as terrestrial radon radiation.

A careful balance is sought between the desire to reasonably protect all persons and the economic impact of tightening exposure limits. First of all, one must determine whether the limits are to be established for a workplace environment with exposures for a constant number of hours per day and a constant number of days per week, only for the working population, or for the rest of the population, possibly living downwind from a chemical manufacturing or rocket testing installation. The general population includes a wider age group and breathes potentially contaminated air around the clock, not only during the 8-h work shift. Statisticians will introduce risk factors at this point, like a risk of one cancer in 1000 to 10000 being considered an acceptable risk for an occupational setting versus a disputed tolerable risk of one in 100000 to 1000000 in the general public. EPA has classified hydrazine as a Group B2 probable human carcinogen. EPA uses mathematical models, based on human and animal studies, to estimate the probability that someone will develop cancer from breathing air containing a specified concentration of a chemical. EPA calculated an inhalation unit risk estimate of  $4.9 \times 10^{-3} \text{ (g/m}^3\text{)}^{-1}$ . EPA estimates that if an individual were to breathe air containing hydrazine at  $0.0002 \text{ g/m}^3$  over his or her entire lifetime, that person would theoretically have no more than a one-in-a-million increased chance of developing cancer as a direct result of breathing air containing this chemical. Similarly, EPA estimates that breathing air containing  $0.002 \mu\text{g/m}^3$  hydrazine would result in no greater than a one-in-a-hundred thousand increased chance of developing cancer, and air containing  $0.02 \mu\text{g/m}^3$  would result in no greater than a one-in-ten thousand increased chance of developing cancer. EPA's Office of Air Quality Planning and Standards, for a hazard ranking under Section 112(g) of the Clean Air Act Amendments, has ranked hydrazine in the non-threshold category. The  $1/\text{ED}_{10}$  value is  $10^7$  per  $(\text{mg/kg})/\text{d}$ , and this would place it in the high category under the Superfund ranking of carcinogenic hazards. Up-to-date information from EPA's Integrated Risk Information System can be downloaded from EPA's web site.

The problem in deciding which exposure limit applies to a certain exposure situation is that there are two to three times as many limits promulgated as there are federal, state, and professional organizations dealing with occupational hygiene, each

of them coming up with their own acronyms, resulting in a proliferation of abbreviations. It may be worthwhile to reference the definitions for each established limit to make sure that the discussion is based on the same set of data. Table 94 shows the exposure guidelines published by authoritative organizations for both groups of the population and for different durations of exposure. The abbreviation for the organization that establishes these limits is shown in parentheses.

**Table 94:** Occupational and general public exposure guidelines.

| Type of exposure         | Type of population    |                       |
|--------------------------|-----------------------|-----------------------|
|                          | Occupational exposure | General public        |
| Short term, emergency    | EEL/EEGL (NAS)        | PEL/SPEL/SPEGL (NAS)  |
| Short term, emergency    | IDLH (NIOSH)          | ERPG-1, -2, -3 (AIHA) |
| Non-emergency short term | STEL (ACGIH)          | STPL (NAS)            |
| Long-term, life-long     | TLV (ACGIH)           | NAAQS (EPA)           |

#### 9.11.1 Occupational Hydrazine Exposure Limits Established for Working Population

Permissible Exposure Limits (PELs) for places of employment are established by OSHA in the US, as published in 29 Code of Federal Regulations Part 1910.1000. Table Z1A of that standard lists several hundred controlled chemicals, including hydrazine, MMH, and UDMH. The first list published by OSHA in response to the Occupational Safety and Health Act of 1970 simply adopted the ACGIH TLVs from the 1968 booklet. The TLV for hydrazine in those days was 1 ppm. The PEL is an enforceable government-imposed limit, but the ACGIH TLV is a voluntary guideline recommended by a professional organization. The 1989 revision of the list in the Z1A table included 600 chemicals. For each chemical, it lists a transitional PEL, a TWA, STEL, and a ceiling limit C that may not be exceeded even if the exposure is compensated by exposure to zero contamination for the rest of the work shift. In addition, several chemicals, including all hydrazines, have a “skin” notation. The TWA is the employee’s average airborne exposure in any 8-h work shift of a 40-h work week that shall not be exceeded. A TWA is a calculation that combines exposure times and concentrations measured throughout the work shift into a single concentration, which is often compared to the TLV to verify one’s compliance. The short-term exposure limit (STEL) is the employee’s 15-min TWA exposure that shall not be exceeded at any time during a workday unless another time limit is specified in a parenthetical notation below the limit. PELs, TWAs, and STELs from the 1989 and most recent version of Table Z1A are summarized in Table 95. The most recent version of Table Z1 is available on the GPO web site [2530]. It is interesting that this table includes phenylhydrazine, which, of course, is eaten by the general population in tonnage quantities as a constituent of agaritine in brown cap mushrooms.

**Table 95:** Time-weighted average and short-term exposure limits.

|                 | Transitional PEL |                   | Skin | TWA |                   | STEL |                   | Ceiling |                   | Skin |
|-----------------|------------------|-------------------|------|-----|-------------------|------|-------------------|---------|-------------------|------|
|                 | ppm              | mg/m <sup>3</sup> |      | ppm | mg/m <sup>3</sup> | ppm  | mg/m <sup>3</sup> | ppm     | mg/m <sup>3</sup> |      |
| Hydrazine       | 1                | 1.3               | X    | 0.1 | 0.1               | —    | —                 | —       | —                 | X    |
| MMH             | C 0.2            | C 0.35            | X    | —   | —                 | —    | —                 | 0.2     | 0.35              | X    |
| UDMH            | 0.5              | 1                 | X    | 0.5 | 1                 | —    | —                 | —       | —                 | X    |

<sup>a</sup> per 29CFR 1910.1000 Table Z1A Data, 1989 Revision

### 9.11.2 Long-Term Exposure Limits Established for the Working Population

The most widely accepted TLVs are those established by the ACGIH. The definition for TLV reads: “Threshold limit values refer to airborne concentrations of substances and represent conditions under which it is believed that nearly all workers may be repeatedly exposed to day after day 8 h/d, 40 h/wk without adverse effect.” Three series of ACGIH publications are particularly useful in establishing and maintaining safe working conditions at places of employment (regardless if the workplace contains hydrazines or not): The annually updated TLV booklet [2531], the less frequently updated and slightly more detailed *Guide to Occupational Exposure Values* [2532], and the most detailed loose-leaf issue of *Documentation of the Threshold Limit Values and Biological Exposure Indices*, a loose-leaf issue in five-ring binders that was, as of 2001, in its seventh edition [2533]. These are the standard reference sources in this field. In the sixth edition of the loose-leaf publication, hydrazine was covered on pp. 761–765, MMH on pp. 1009–1012, and UDMH on pp. 491–494. These loose-leaf summaries are the best way to get started on a hydrazine occupational hazards/toxicity study, and they provide a useful number of references. Most of these documents are available from ACGIH not only on paper, but also on CD-ROM or diskette in electronic, easily searchable format. ACGIH has a web site where some of the information can be downloaded. Because regulations change so frequently, some of them every year, this is the most efficient way to stay up to date. The TLV booklet, which for many years was small enough to fit into a shirt pocket as the indispensable *vade mecum* of an industrial occupational hygienist, has now grown to a spiral-bound book format that no longer fits into a shirt pocket. Maybe the database stored in a smartphone computer will eventually take its place. See also [2534].

It is of interest to follow the historical evolution and tightening of hydrazine occupational exposure limits in various industrialized countries of the world. It appears that as soon as one country lowered the exposure limit, other countries would follow suit. This is a direct result of close international cooperation, where many safety issues, e.g., transportation classifications, are now handled by international agencies like UNO or EEC. Other countries where publications dealing with hydrazine TLVs are on record include France [2535], UK [2536], and Germany. The German Committee for

Hazardous Substances at the Workplace (AgA) in 1982 established a recommended threshold limit concentration (TRK) for 14 proven or suspect carcinogens, including hydrazine. The recommended upper limit for hydrazine was 0.1 ppm [2537].

It has often been shown that occupational exposure limits (OELs) for the same substance can vary significantly between different standard setters. An attempt was made to identify the steps taken by various agencies in the often arbitrary process toward establishing an OEL and how variations in those processes could account for these differences [2538]. This study selected for further scrutiny substances for which the OELs varied by a factor of 100, focusing on 14 substances from 8 standard setters. Like the hydrazine data, several of the OELs studied were more than 20 years old and based on outdated knowledge. Furthermore, different standard setters sometimes based their OELs on different sets of data, and data availability alone could not explain all differences in the data selected by standard setters.

The case of hydrazine hydrate poisoning in Finland that led to the death of a boiler operator [2498] caused authorities in Finland to issue tighter regulations about chemical exposures in the workplace. Health authorities in other countries, such as Germany [2539, 2540], have followed suit and tightened their regulations on the use of hydrazine in boiler feedwater treatment installations in power plants. At the same time, hydrazine solution producers have provided shipping and transfer containers, which allow for the hermetically sealed transfer of solutions, minimizing operator exposure.

A publication by the International Labor Office compares established limits in 15 countries and gives examples of the different criteria adopted by different countries in establishing their domestic exposure limits. Another suspected reason for the continued tightening of long-term exposure limits is that in the past, previously available analytical methods were not capable to reliably and rapidly measure contaminant concentrations in air. It appears that as soon as a more sensitive analytical method became available, the tolerable level for that particular chemical was lowered, placing a new challenge on the sensitivity and accuracy of the analytical instrumentation. Detection limits and tolerable levels have been in a “leapfrogging” mode for several decades. Some governments have issued a rule stating that carcinogens should be kept below detectable levels, which makes the tolerable concentration a variable dependent on the analytical technique used. As of 1991, the maximum allowable concentrations (equivalent to our TLV) in other countries were as summarized in Table 96.

Table 2 on page 12 of the recommendation from the European Scientific Committee on Occupational Exposure Limits for hydrazine contains a summary of occupational exposure limits for many countries in the world [2542–2544]. A complete table listing the 8-h and short-term exposure limits in 24 countries is available online at the German Institute for Worker Protection, part of the federal workmen’s compensation accident insurance [2545], although that table does not indicate when it was last updated. So far, only Japan has issued specific limits for hydrazine hydrate, which should have

**Table 96:** Maximum allowable concentrations in other countries, ppm (equivalent to TLV).

| Country               | Hydrazine                                             | MMH                                                          | UDMH                                                                     |
|-----------------------|-------------------------------------------------------|--------------------------------------------------------------|--------------------------------------------------------------------------|
| Germany (1991)        | 0.1, Group A2 <sup>a</sup> , skin, sensitizer; [2541] |                                                              | no MAK established, Group A2 <sup>a</sup> , skin, sensitizer             |
| Australia (1990)      | 0.1                                                   | 0.2 short term peak 15 min limitation, Category 3 carcinogen | 0.5 short term, Category 2 probable human carcinogen, skin, under review |
| Sweden (1989)         | 0.1 (short term 0.3)                                  |                                                              | 0.1; 15-min STEL 0.2 ppm, skin, carcinogenic (1984)                      |
| United Kingdom (1991) | 0.1 skin                                              |                                                              | no limit established, carcinogen                                         |

<sup>a</sup> A2 = unmistakably carcinogenic in animal experimentation only

been done by all countries because the hazard with anhydrous hydrazine inhalation would be different from that with hydrazine hydrate.

The American Conference of Governmental Industrial Hygienists (ACGIH) grades hydrazine as “A3 – confirmed animal carcinogen with unknown relevance to humans.” TLVs for hydrazines as established by ACGIH are summarized in Table 99. The 8-h/d, 40-h/week TLV for hydrazine was lowered in 1995 from 0.1 to 0.01 ppm. Figure 69 illustrates the historical evolution of TLVs for hydrazine in the US during the past several decades, lowering the TLVs by several orders of magnitude. The scientific rationale for lowering the TLV has been questioned, and the cost:benefit ratio fails to show a reasonable justification.

**Figure 69:** Historical evolution of hydrazine TLV.

Significant discussions were held among a worldwide group of hydrazine manufacturers (a so-called hydrazine coalition), hydrazine users, and governmental regulatory agencies during the early 1990s when it was proposed to lower the TLV from 0.1 to 0.01 ppm. An industry/government team of toxicologists met several times and reviewed the available evidence, which was quoted in support of a request to lower the TLV [2546]. The difficulty was that most of the data cited in making that decision were quite antiquated and typically 20 years old. There were insufficient funds to repeat the inhalation exposure tests with hundreds of animals and with more accurate measurement of the actual vapor concentrations in the exposure chambers.

The impetus for the ACGIH proposal to lower the TLV was based on an outdated 1985 report on animal exposures done during the preceding 10-year period, 1975–1985 [2394]. It reported a slightly elevated incidence of nasal tumors in rats exposed to *what was intended to be* 0.05 ppm hydrazine for 1 year (6 h/d, 5 d/week) and held for 1 year post-exposure as compared to unexposed controls. The words *what was intended to be* require explanation: There were obvious experimental errors in the vapor exposure techniques used several decades ago, foremost among them the use of very long sampling lines between the many external animal cages and a single, central vapor concentration measuring station. It was later shown that hydrazine and UDMH absorbed irreversibly, permeated, and decayed in sampling lines made of various materials [1870, 1871, 2547]. The introduction of a considerable excess of hydrazine into the animal exposure chambers was required to attain the desired vapor in air concentrations at the end of a long sampling line (see Section 9.6.1 “Acute Inhalation Hazard Studies” [2394]). The total intake by the animals was increased by hydrazine that had adsorbed on the food and because the animals often licked their hydrazine-soaked fur. Despite being aware of these metering errors, a government study group concluded in 1994 that “All procedures used in the study and the data regarding exposures of the animals were found to be valid and consistent with the technologies available at the time of the study in 1976.”

Considerations for a rational approach to arriving at a safe limits of occupational exposure of workers would differ from those applied for general public exposure [2548]. Experimental uncertainties about antiquated animal exposure data make it difficult to arrive at a decision that could have significant economic impact on the industry, yet the number of individuals at risk is relatively small.

The ACGIH TLV committee did not include a quantitative cancer risk assessment in setting the 1995 TLV at 0.01 ppm. The risk associated with the new TLV has been estimated to be on the order of 2 in 1000, which is consistent with the risk associated with other suspected human carcinogens regulated by OSHA [2548]. However, these risk levels are higher than the criteria used by OSHA to classify “insignificant” risk, which is 1/10000. If that acceptable risk were used, the hydrazine TWA would have to be 0.4 ppb.

Hydrazine is used in various industries in Poland, where as of 2011 approximately 2000 people were assumed to be exposed to hydrazine and its salts [2549]. Until

2015, in Poland, TWA of  $0.05\text{mg}/\text{m}^3$  and STEL of  $0.1\text{mg}/\text{m}^3$  were in effect. The European Union proposed a binding BOELV value of  $0.013\text{mg}/\text{m}^3$ . The LoAEL value is  $0.332\text{mg}/\text{m}^3$ . The derived limit value is  $0.014\text{mg}/\text{m}^3$  and the STEL value is  $0.042\text{mg}/\text{m}^3$  because of the irritant effects. After discussion and voting at the 77<sup>th</sup> meeting of the Interdepartmental Commission for Maximum Admissible Concentrations (MAC) and Maximum Admissible Intensities (MAI) (January 14, 2015), an exposure limit value TWA of  $0.013\text{mg}/\text{m}^3$  and a STEL value of  $0.039\text{mg}/\text{m}^3$  were accepted.

### 9.11.3 Biological Exposure Indices

Ideally, in addition to wearing dosimeters that indicate the cumulative exposure to hydrazines during a work shift, it would be desirable to have BEIs, for instance, hydrazine concentration in the urine or plasma of workers measured before and at the end of each work shift, which can be correlated with the exposure profile. However, most hydrazines are metabolized too fast to serve as an indicator. Sensitivity of analytical methods for hydrazine in urine or plasma is insufficient to serve as a routine analysis in place of a dosimeter or in addition to a dosimeter. If hydrazine or MMH or UDMH as measured using current instrumentation started showing up in the urine, one would already have a serious poisoning incident at hand. This approach to BEIs works only with less reactive chemicals, such as halogenated solvents or benzene.

### 9.11.4 Information Relevant for Occupational Health Standards

Government regulators depend on published information to establish limits. In a survey of information relevant to occupational health standards for hydrazines, several hundred references on hydrazine, MMH, and UDMH toxicity have been compiled [2304]. At that time, the main concern in this study was to gather evidence that would support or dispute the proposal by ACGIH to lower the TLV for hydrazine from 1.0 to 0.1 ppm and to place it and other methylhydrazines on the list of suspected carcinogens. In addition, the search was extended to *N*-nitrosodimethylamine (a one-time intermediate in the production of UDMH and a known carcinogen) and nitrosomethylurea and nitrosomethylurethane, intermediates of a proposed but never used alternative UDMH production process. A similar effort by NIOSH in 1978 resulted in a document titled *Criteria for a Recommended Standard* [2291] in which NIOSH recommended to lower the TLV for hydrazine from 0.1 to 0.03 ppm.

### 9.11.5 Emergency Exposure Limits for Hydrazine Exposure

Emergency exposure limits for hydrazines were established by the Committee on Toxicology, National Research Council, National Academy of Sciences (NAS-NRC); they were defined as follows: “The Emergency Exposure Limit for short-term exposure to

an airborne contaminant is a concentration which, when inhaled for a specified single brief period, rare in the lifetime of an individual, is believed not to result in a period of disability or interfere with the performance of his assigned task" [2550–2553].

The EEL was established for healthy young males under close medical supervision. Emergency exposure limit data are available only for a fraction of all those chemicals for which TLVs were established. Limited data are available for hydrazine and methylhydrazines [2554–2556]. EELs for hydrazines as recommended by the NAS-NRC are listed in Table 99 along with the TLVs. As can be seen from this table, the ratio between EEL (10 min) and TLV valid at that time varies from 200 to 30, depending on the fast-acting nature of the compound. Hydrazine as a fast-acting skin and mucous membrane irritant has been given a low EEL in comparison to UDMH, which is more a systemic poison (but UDMH has a higher vapor pressure!).

In addition to establishing an EEL, some agencies have begun to collect information and publish information on the immediately dangerous to life and health (IDLH) concentrations of fast-acting acute poisons [2557]. The IDLH documentation is also available in the form of a NIOSH Pocket Guide to Chemical Hazards [2558]. The criteria used by the commission in setting the IDLH limits are described in [2559].

The NIOSH/CDC home page has IDLH information posted for hydrazine and MMH. The recommended limits are summarized in Table 97 in comparison with several other commonly used hazardous chemicals.

**Table 97:** Immediately dangerous to life and health limits for hydrazines.

| Compound        | Original IDLH (SCP), ppm | Revised IDLH, ppm | Date posted     |
|-----------------|--------------------------|-------------------|-----------------|
| Hydrazine       | 80                       | 50                | August 16, 1996 |
| MMH             | 50                       | 20                | August 16, 1996 |
| For comparison: |                          |                   |                 |
| Ethanol         | 15000                    | —                 | August 16, 1996 |

Data source: NIOSH Web Page at <http://www.cdc.gov/niosh>

Acute exposure threshold levels (AETLs) for the general population in Europe were developed in the context of the risks of major accidents from chemical sites such as the Seveso or Bhopal accidents [2560]. Twenty-one substances were selected to be used as preliminary case studies in the development and testing of the AETL methodology, and the development of a prioritization methodology to support initial substance selection for a possible further AETL program. In discussion with a critical review panel and ACUTEX experts, hydrazine was selected because it had appropriate data and was in relatively widespread use in the EU, but no specific numbers were given.

### 9.11.6 Hydrazine Exposure Limits Established for General Population

It is generally assumed that exposure of workers at their place of employment is at least partially voluntary, because workers can choose where to work. The general public does not have that choice and has the right to clean air even if they live downwind of a chemical installation. Quite often exposure limits are extrapolated from occupational TLVs to non-occupational exposure conditions without due consideration of the different populations involved. The need to protect the population at large from disastrous or chronic exposures gained legislative momentum as the result of EPCRA, enacted as Superfund Amendments and Reauthorization Act of 1986, which is SARA Title III, and CERCLA, also part of Superfund. SARA Title III requires local authorities to develop emergency response plans to deal with accidental release of extremely hazardous substances in their communities. This was partially prompted by Seveso- or Bhopal-type accidents in chemical plants that had severe impacts on the surrounding communities. “Extremely hazardous substances” are defined in 40 CFR Part 355 issued by EPA [2561]. That list contains more than 400 chemicals, including hydrazine, MMH, and UDMH. The reportable quantity of hydrazine is 1 lb (453 g). Oddly enough, the table does not include hydrazine hydrate and does not specify the type of dimethylhydrazine (1,1- or 1,2-). This indicates a poor understanding of chemistry on the part of the people assembling this table.

A STPL of 5.3 ppm (7 mg/m<sup>3</sup>) and a 30-min PEL of 20 ppm (20 mg/m<sup>3</sup>) were used as examples to determine the hazard corridor downwind from hydrazine spills [1969, 1970]. Additional STPL and PEL data are summarized in Tables 98 and 99. The AEGL limits (see below) are intended to replace the old SPEGL limits for hydrazines issued by the NRC on earlier occasions, which are now obsolete (from the NIOSH-CDC web page, like IDLH listings).

The National Advisory Committee on Acute Exposure Guideline Levels (AEGLs) was established to identify, review, and interpret relevant toxicological and other scientific data and develop AEGLs for high-priority, acutely toxic chemicals. AEGLs represent ceiling exposure values for the general public and are applicable to emergency exposure periods ranging from less than 1 to 8 h. Three AEGLs apply to each of four exposure periods (30 min, 1, 4, and 8 h) and are distinguished by varying degrees of severity of toxic effects. The three AEGLs have been defined as follows:

**AEGL-1** is the airborne concentration (expressed as ppm or mg/m<sup>3</sup>) of a substance at or above which it is predicted that the general population, including “susceptible” but excluding “hypersusceptible” individuals, could experience notable discomfort. Airborne concentrations below AEGL-1 represent exposure levels that could produce mild odor, taste, or other sensory irritations. Below AEGL-1, the criterion is detectability: a chemical can be perceived only by smell, taste, sight, or mild sensory irritation.

**AEGL-2** is the airborne concentration of a substance at or above which it is predicted that the general population, including “susceptible” but excluding “hypersusceptible” individuals, could experience irreversible or other serious, long-lasting effects or impaired ability to escape. Airborne concentrations below AEGL-2 but at or

above AEGL-1 represent exposure levels that may cause notable discomfort. Below AEGL-2, physical discomfort is the key factor; exposure does not impair escape, produce disablement or disorientation, or result in permanent or long-lasting effects.

**AEGL-3** is the airborne concentration of a substance at or above which it is predicted that the general population, including “susceptible” but excluding “hypersusceptible” individuals, could experience life-threatening effects or death. Airborne concentrations below AEGL-3 but at or above AEGL-2 represent exposure levels that may cause irreversible or other serious, long-lasting effects or impaired ability to escape. Disability can ensue, and external assistance is needed because people can become disabled and disoriented as a result of exposure or experience permanent or long-lasting residual effects. Above AEGL-3, life-threatening effects or death can occur either immediately or shortly after exposure.

Proposed AEGLs for hydrazine, MMH, and UDMH were published in 1997. The criteria document for hydrazine spans 56 pages and contains 49 references. AEGLs proposed for hydrazines are summarized in Table 98.

#### **9.11.7 Exposure Limits Established for Special Skin-Only Conditions**

Most inhalation exposure limits are established for simultaneous inhalation and whole-body exposure. Attempts have been made to replace the bulky SCAPE suits with supplied air respirators, providing clean air for breathing but leaving the skin exposed to potentially toxic vapors. Skin permeation of hydrazine and UDMH vapors has been measured (Section 9.6.4.1), and a pharmacokinetic model was used to calculate the vapor concentration to which propellant handlers with supplied air respirators may be exposed and still meet the TLV limitations for inhalation as far as the total body dose is concerned [2565, 2566]. The calculations showed that the vapor concentration during a skin-only exposure would have to be at least 200 times higher than that during inhalation to cause the same level of poisoning. For the old TLVs for hydrazine and UDMH of 0.1 and 0.5 ppm, the equivalent skin-only tolerable concentration would have been 48 ppm for hydrazine and 32 ppm for UDMH. For the new TLVs of 0.01 ppm, the equivalent skin-only TLVs would be 4.8 ppm for hydrazine and 0.64 ppm for UDMH.

#### **9.11.8 Effects of Long-Term Exposure to Hydrazine in Closed Environments**

The 8 h/d, 40 h/week exposure cycles are quite different from that of astronauts working and living in space stations or navy personnel in submarines. A different set of criteria must be generated for these conditions. Spacecraft Maximum Acceptable Concentrations (SMACs) are being established by NASA for potential contaminants in closed environments [2567]. A draft table of derived SMACs was submitted to the NRC Committee on Toxicology for review before implementing the new limits on all future space flights [2305, 2568, 2569]. Derived SMAC concentrations for hydrazine

**Table 98:** Proposed AEGL values for hydrazines (Proposed in 1997).

| Chemical  | Classification      | Limit | 30-min                              | 1-h                                 | 4-h                                 | 8-h                                 | Endpoint                                                                               | References   |
|-----------|---------------------|-------|-------------------------------------|-------------------------------------|-------------------------------------|-------------------------------------|----------------------------------------------------------------------------------------|--------------|
| Hydrazine | AEGL-1 <sup>a</sup> |       | 0.1 ppm<br>(0.1 mg/m <sup>3</sup> ) | 0.1 ppm<br>(0.1 mg/m <sup>3</sup> ) | 0.1 ppm<br>(0.1 mg/m <sup>3</sup> ) | 0.1 ppm<br>(0.1 mg/m <sup>3</sup> ) | Eye and facial irritation in monkeys                                                   | [2562]       |

|           | AEGL-3              |       | 47 ppm<br>(61 mg/m <sup>3</sup> )   | 33 ppm<br>(43 mg/m <sup>3</sup> )   | 17 ppm<br>(22 mg/m <sup>3</sup> )   | 12 ppm<br>(16 mg/m <sup>3</sup> )   | Lethality in rats                                                                      | [2399]       |
| MMH       | AEGL-1              |       | N/A                                 | N/A                                 | N/A                                 | N/A                                 | N/A <sup>b</sup>                                                                       |              |
|           | AEGL-2              |       | 2 ppm<br>(3.8 mg/m <sup>3</sup> )   | 1 ppm<br>(1.9 mg/m <sup>3</sup> )   | 0.2 ppm<br>(0.4 mg/m <sup>3</sup> ) | 0.1 ppm<br>(0.2 mg/m <sup>3</sup> ) | Three-fold reduction in AEGL-3                                                         |              |
|           | AEGL-3              |       | 6 ppm<br>(11.3 mg/m <sup>3</sup> )  | 3 ppm<br>(5.6 mg/m <sup>3</sup> )   | 0.7 ppm<br>(1.1 mg/m <sup>3</sup> ) | 0.3 ppm<br>(0.6 mg/m <sup>3</sup> ) | 1-h LC <sub>50</sub> of 82 ppm reduced 3-fold to estimate a lethality threshold        |              |
| UDMH      | AEGL-1              |       | N/A                                 | N/A                                 | N/A                                 | N/A                                 | N/A <sup>b</sup>                                                                       |              |
|           | AEGL-2              |       | 6 ppm<br>(14.7 mg/m <sup>3</sup> )  | 3 ppm<br>(7.4 mg/m <sup>3</sup> )   | 0.8 ppm<br>(2 mg/m <sup>3</sup> )   | 0.4 ppm<br>(1 mg/m <sup>3</sup> )   | Behavioral changes and muscle fasciculations in dogs exposed to 360 ppm for 15 minutes | [2563, 2564] |
|           | AEGL-3              |       | 22 ppm<br>(54 mg/m <sup>3</sup> )   | 11 ppm<br>(27 mg/m <sup>3</sup> )   | 3 ppm<br>(7.4 mg/m <sup>3</sup> )   | 1.5 ppm<br>(3.7 mg/m <sup>3</sup> ) | Lethality threshold of 327 ppm for 1 h estimated from 1-h LC <sub>50</sub> in dogs     | [2563, 2564] |

<sup>a</sup> Because the contact irritation response to the extremely reactive hydrazine is concentration dependent rather than time dependent, the AEGL-1 is the same for all time periods.

<sup>b</sup> Inappropriate because notable toxicity may occur at concentrations below the odor threshold (see text)

exposures for 1 h to 30 d were all above the new 1996 TLV of 0.01 ppm, which applies to NASA workers on the surface of the Earth. Only the proposed 180-d limit of 0.004 ppm was below the current TLV. For MMH, SMAC limits of 0.002 ppm were proposed for all exposure durations, because a different metabolic mechanism/target organ is involved. While one would intuitively expect that the toxicities of hydrazine and MMH would be similar, NASA toxicologists arrived at quite disparate SMAC values.

### 9.12 Olfactory Threshold of Hydrazine Vapors

There is a wide discrepancy in reported olfactory threshold values for hydrazine itself. Several sources agree that one should not rely on the odor of hydrazine as a warning for imminent acute or subacute exposure because it may cause olfactory fatigue. Also, the olfactory threshold is far above the established safe levels. Table 99 summarizes the reported olfactory threshold of hydrazines in comparison to former and current TLV and EEL TLVs.

It is interesting to compare odor thresholds for hydrazines and ammonia with those of 214 other industrial chemicals [2573]. Hydrazine is not easily identified by its odor. The olfactory threshold for hydrazine in air is 3.7 ppm, that for ammonia is 5.2 ppm, and that for MMH or UDMH is 1.7 ppm. Methylhydrazines have a more distinct fishy odor, although it would be difficult to differentiate them from methylamine or dimethylamine, common constituents of fish degradation products.

### 9.13 Medical Surveillance Protocols for Monitoring Hydrazine Propellant Handlers

Personnel anticipated to work routinely with hydrazines should undergo thorough entry medical exams. The following pre-existing medical conditions are contraindications for working with hydrazines and would aggravate the results of inadvertent exposure: pregnancy, anemia, hematological disorders, history of convulsive episodes and other neurological disorders, "slow acetylator" phenotype, glucose-6-phosphate dehydrogenase deficiency, 6-phosphogluconic dehydrogenase deficiency, glutathione reductase deficiency, therapeutic use of tranquilizers, and existence of any tumors, benign or not. For USAF personnel, Air Force Occupational Safety and Health (AFOSH) Standard 48-8, Attachment 8, [2574] reviews the considerations for occupational exposure to hydrazine in missile, aircraft, and spacecraft systems, specifies the selection criteria for personnel potentially exposed to hydrazine, and establishes a medical surveillance routine and record-keeping requirements [2575]. Industrial and academic organizations working with hydrazines may want to adopt similar plans.

Table 99: Olfactory threshold and exposure limits for hydrazines.

| Type of data <sup>a</sup> | Hydrazine      | References | MMH            | References   | UDMH           | References   |
|---------------------------|----------------|------------|----------------|--------------|----------------|--------------|
| Olfactory Threshold       | 69–83          | [2570]     | 1–3            | [2570, 2571] | 0.5–1.0        | [2572]       |
| Olfactory Threshold       | 3–4            | [2571]     |                |              | 6–14           | [2571]       |
| ACGIH-TLV (1981)          | 0.1 (skin)     | ACGIH      | C 0.2 (skin)   | ACGIH        | 0.5 (skin)     | ACGIH        |
| ACGIH-STEL (1981)         | —              | ACGIH      | —              | ACGIH        | 1              | ACGIH        |

<sup>a</sup> All data in ppm by volume.

### 9.14 Toxicity of Hydrazine Mixtures

Many hydrazine mixtures have been used as rocket propellants, foremost among them is Aerozine-50, the 50 : 50 mixture of hydrazine and UDMH. Since the inhalation toxicity of this mixture is mostly dominated by that of the more volatile UDMH, the toxicity of this mixture is discussed in *Encyclopedia of Liquid Fuels* in the chapter “Dimethylhydrazines.”

One of the first hydrazine mixtures to be used as a rocket propellant in the US was a ternary blend of hydrazine, aniline, and furfuryl alcohol. This blend was used in sounding rockets developed by JPL and Aerojet. The acute and chronic inhalation toxicity of this propellant was tested in animal experiments [2576], and hydrazine was the most toxic constituent of this mixture.

## 10 Environmental Fate and Effects

In view of growing public concern over the environmental effects of hazardous chemicals, and in view of increasing legislative action aimed at the control of chemical hazards, it is important to have a section dedicated to the environmental effects of hydrazine and its derivatives. This information can generally be derived from other paragraphs on toxicity, autoxidation, and so on, but it is worthwhile to consider hydrazine chemistry from the standpoint of an environmental scientist.

Fortunately, and in contradistinction to polychlorinated biphenyl (PCB), dioxin, or dichlorodiphenyltrichloroethane (DDT), little can be said about the environmental persistence of hydrazine and hydrazine derivatives because they degrade so rapidly under the effect of air (oxygen), light, and soil bacteria [2577]. This is one of the most distinct advantages of hydrazine-derived chemicals in numerous agricultural and industrial applications as pesticides, boiler feedwater treatments, or anti-corrosion additives. The biodegradability of hydrazine derivatives is one of the reasons that some hydrazine-based pesticides have been chosen to replace more persistent, chlorinated, or thiophosphate-ester organics that may accumulate in the food chain and/or are suspect endocrine disruptors.

Under the sponsorship of the USAF Civil and Environmental Engineering Development Office (CEEDO, later AFESC-ESL) at Tyndall AFB in Florida, a series of conferences on the environmental chemistry of hydrazine fuels was held in 1977, 1979, and 1987. The proceedings from these three meetings constitute a valuable resource for studying the environmental effects of hydrazine fuels [2578–2580]. During the period in which these conferences were held, the number of industrial and military uses of hydrazines increased substantially [3], and numerous studies on environmental and health effects of hydrazines were in progress [2581]. The concern over hydrazine toxicity eventually led to a lowering of the TLVs for hydrazine exposure at the workplace and to a heightened awareness of the occupational and environmental hazards

of hydrazines. During the period from 1970 through 1985, the USAF Medical Research Laboratory hosted a series of *Annual Conferences on Environmental Toxicology*. Some of these conferences contained several individual papers on hydrazines, although in other years some of these conferences did not deal with hydrazines at all.

The US Environmental Protection Agency (EPA) has issued several *Health and Environmental Effects Profiles* for hydrazines that contain sections on environmental effects in addition to toxicity information [2292]. Howard's *Handbook of Environmental Degradation Rates* gives data for many chemicals, including hydrazine, MMH, UDMH, SDMH, and NDMA [2582].

### 10.1 Potential Environmental Impact of Hydrazine

When hydrazines and hydrazine derivatives were first introduced for a variety of applications, some of which were agricultural applications where it must be expected that crop residues will end up in consumer food, there was little and insufficient understanding of the potential environmental and consumer health implications. This awareness has changed greatly in recent decades. The persistence of hydrazine derivatives in the environment is low compared to other xenobiotic toxicants that have caused similar concern, e.g., DDT or dioxin. Nevertheless, adequate precautions need to be taken to avoid environmental pollution.

Prior to the introduction of the F-16 fighter jet, hydrazine propellants were used only in a small number of rocket launch sites. When the F-16 was introduced, it caused hydrazine (in the form of a 70% aqueous solution) to enter the logistics chain and had to be stored at many airbases, including forward bases during military conflicts. Although thorough planning and preparation of environmental impact statements preceded the introduction of the F-16 [2509], the complexity of the task was underestimated, and the acceptance of the new technology by flight-line maintenance personnel was not unequivocally enthusiastic. Despite the poorly planned fielding of a new hazardous fluid and lack of training in many cases, there were only a few incidents of spillage and accidental vapor exposure. The few incidents that did occur caused the USAF to push for lowered TLVs in the entire industry, although industry knew very well how to safely handle this chemical.

Additional information on the environmental effects of hydrazines is available in [22] including the aquatic toxicity and degradation of hydrazine in water, degradation of hydrazine in surface waters and in sewage treatment plants, adverse effects of hydrazine on plants, hydrazine degradation and environmental fate in soil, and atmospheric decay of hydrazine vapors in air. These sections of the recommended standard reference for information on hydrazine toxicity and environmental effects have not yet been updated.

## 10.2 Environmental Pollution Case Studies

Hydrazines have been used for more than half a century in a wide range of rocket propulsion applications in addition to many commercial applications. It is unfortunate that some locations have experienced pollution incidents in which hydrazines may have entered the environment.

Launch mishaps like the Titan 34D explosions just offshore in California on August 28, 1985, and April 18, 1986, and a later Titan 4A explosion on August 12, 1998, off the coast of Florida resulted in the release of a large cloud of unburnt liquid propellant in the midst of chunks of burning solid propellant. Atmospheric models have been derived to predict the path of the toxic cloud, the chemical reactions in the cloud, and the downwind concentrations where it begins to enter populated areas. The more visible part of these events was the aluminum oxide and hydrogen chloride from the solid propellant boosters and the red cloud from evaporating NTO converting itself to nitrogen dioxide. The Aerozine-50 propellant that may also have been involved in the deflagration was less visible.

A spill of commercial hydrazine hydrate from 16 punctured steel drums in a railroad accident near Sea Cliff, CA, occurred on July 28, 1991. No major environmental damage occurred since the spill site was quickly surrounded by a dam, and leaked hydrazine hydrate was collected in a lined pond and destroyed with hypochlorite solutions.

Several decontamination techniques were used to clean up the stored process waste and tank rinse water from the Rocky Mountain Arsenal Hydrazine Blending and Storage Facility [2023]. Significant NDMA levels persisted in the groundwater below Rocky Mountain Arsenal for many years after the propellant mixing facility was shut down. Air sampling at Rocky Mountain Arsenal Hydrazine Blending Facility continued for several more years while the cleanup was in progress [2064, 2519, 2520]. Intercept wells were sunk to prevent polluted groundwater from diffusing off-site. NDMA-contaminated water collected in these wells could not be cleaned by activated charcoal filters alone.

During the development and production of the TITAN II ICBM, large quantities of Aerozine-50 were consumed at a test site near Denver, CO, which was initially intended for the use of LOX/kerosene only. Many years after the test facilities were decommissioned and contamination from halogenated solvents was found, the USAF started a facility restoration program to make sure that no pollutants would spread from the sites [2583, 2584]. The Agency for Toxic Substances and Disease Registry (ATSDR) evaluated environmental data and exposure information associated with the Air Force Plant PJKS site and determined that the site posed no apparent public health hazard [2585].

### 10.3 Effect of Anhydrous Hydrazine on Bacteria Viability

The concern arose that anhydrous hydrazine in propellant tanks that crash or vent on other planets might harbor terrestrial bacteria that would then propagate on the target planet in their new environment, resulting in false findings of future search for extraterrestrial life. For the purposes of planetary protection, a series of experiments was performed to answer a long-standing question about the potential of bacterial contamination of interplanetary spacecraft from liquid hydrazine residues in propellant tanks vented or crashed on Mars. Spores of *Bacillus atrophaeus* (ATCC No. 9372, also known as *Bacillus subtilis* var. *niger*, and BSN) were exposed to anhydrous hydrazine and survivors were enumerated using the NASA standard planetary protection pour plate assay [2586]. Results indicated that bulk hydrazine rocket propellant may be considered free of living bacterial cells for planetary protection compliance.

Similar results were obtained with bacteria cultures exposed to hydrazine vapor [2587]. The exposure times required to reduce the spore population by a factor of 10, known as the *D*-value, were  $4.70 \pm 0.50$  h at 298 K (25°C) and  $2.85 \pm 0.13$  h at 308 K (35°C). These inactivation rates are short enough to ensure that the bioburden of the surfaces and volumes in a space probe would be negligible after prolonged exposure to hydrazine vapor. Thus, not all of the propellant tubing and internal tank surfaces exposed to hydrazine vapor contribute to the total spore count in hardware sent to other planets.

### 10.4 Atmospheric Dispersion, Decay, and Environmental Fate of Hydrazine

#### 10.4.1 Atmospheric Dispersion of Hydrazine

In the event of a spill and uncontrolled release of hydrazine(s) into the air, the immediate concern is for the safety of the population in the surrounding community. Instructions will need to be given to the hazardous material response team on how wide the evacuation circle should be drawn, depending on the size of the spill, the toxicity of the materials, the meteorological conditions, and the toxicity of the material.

A detailed summary of hazard corridor computer models has already been provided in Section 7.8.3. The models discussed there do not take into consideration that hydrazines react with oxygen in the air and become oxidized and photolyzed while they disperse. Another mode of neutralization is by the reaction of hydrazine with atmospheric carbon dioxide, leading to carbazic acid, a solid of very low volatility that most likely would precipitate as an aerosol, especially on a moist day. Therefore, the predicted hydrazine concentrations at the perimeter of the vapor plume are most likely higher than the actual measurements would show. It has been recommended that future improvements of atmospheric dispersion models include not only dilution, diffusion, and meteorological parameters, but also chemical reactions that could lead to a more rapid decay of hydrazines in the atmosphere [2588, 2589].

In the unusual situation that 1040 kg (2300 lb<sub>m</sub>) of hydrazine flown as part of an auxiliary power generator on board a military aircraft should have to be dumped in case of an emergency, dispersion profiles were calculated for a planned dump (requiring < 5 min) and an emergency dump (lines and pressurization sized for the fastest possible dump within less than 1 min.) [1927].

#### 10.4.2 Hydrazine Dispersion in Atmosphere from Re-entering Spacecraft

A rare case of hydrazine dispersion is the disintegration of satellites or upper stages that still contain varying amounts of residual hydrazine(s), either liquid or even frozen solid. This concern surfaced in 2008 when it became known that a wayward, uncontrollable US military satellite known as US193 that was about to re-enter the atmosphere contained a large tank with 450 kg (1000 lb) anhydrous hydrazine that was most likely frozen because the temperature controls on the satellite were inoperative. It was not possible to predict the time and location of re-entry, but in the worst case it could have re-entered over populated areas. If experts could have assured the authorities that the propellant was not frozen, the liquid propellant would more likely have dispersed in the atmosphere before it hit the ground. Numerous calculations were performed to estimate the chance that the tank and its contents would survive re-entry. One calculation predicted that the titanium shell of the tank would be breached due to re-entry heating and melting, but its frozen contents would not melt fast enough to disperse all the liquid before the tank would hit the ground [2590]. The model would have to be improved by entering the heat capacity of the solid and liquid hydrazine as a function of temperature (instead of a constant number) and by dividing the hydrazine model into several layers instead of one bulk mass. To be on the safe side, the out-of-control US193 satellite was destroyed in orbit by hitting it with an anti-missile missile launched from a ship. The US193 satellite that was destroyed in 2008 by an SM-3 antimissile interceptor at an altitude of 209 km (130 miles) in order to prevent it from re-entering the atmosphere above populated areas, involved most likely frozen hydrazine, and not methylhydrazine [2591].

Any aerodynamic re-entry heating that is enough to heat the second stage structures to beyond the melting point of metals, as evidenced by the meteor-like brightly shining object in the video of a re-entering second stage, is hot enough to destroy any remaining propellant on board. Re-entering first stages remain intact to the point that local residents in the impact area make a business out of salvaging the scrap metal. Looking at the debris collected on the ground from the disintegration of Space Shuttle Columbia during re-entry, spherical tanks are more likely to survive entry intact than other components [2592]. Some of the spherical tanks shown in NASA pictures tied down on a flatbed truck could have been just pressurant gas tanks and not liquid propellant tanks. It is not known whether any of the other tanks were tested for residual propellants that might have survived the re-entry heating. As part of a “design for demise” philosophy, a tankage re-entry survival analysis was performed for the

re-entry of NASA's Global Precipitation Measurement satellite [1690] and other satellites [2593].

A survivability-analysis program has been developed to analyze the ground impact risk of atmospheric re-entry objects, such as satellites or the upper stages of a launch vehicle, which move at or near the orbital velocity [2594]. The aero-thermodynamic load during free fall, the temperature variation due to thermal load, and the phase change after reaching the melting point were integrated into the three-degree-of-freedom trajectory simulation of the re-entry objects to analyze the size and weight of debris surviving re-entry and impacting the ground. The analysis results of the present method for simple-shaped objects were compared with the data predicted by similar codes developed by NASA and ESA and compared to observed actual re-entry orbital objects found on the ground.

The influence of oxidation on the thermal degradation process and material properties under atmospheric entry conditions remains unknown. An experimental investigation examining Ti-6Al-4V oxidation under atmospheric entry conditions was made in a 6-kW solar furnace, as most of the debris found on the ground was made of this material [2595, 2596]. The computer code was applied to the atmospheric re-entry of a generic Ti-6Al-4V tank and would be applicable to all tanks, those containing hydrazine or other propellants.

The controlled release of clouds of rocket propellants in space was planned to be studied during the chemical release experiment flown as payloads in the Space Shuttle payload bay [2597]. The purpose of this experiment was to identify the potential environmental consequences of an inadvertent release of hydrazine rocket propellant in space, during orbital or suborbital operations. The experiment was to be conducted in the thermosphere of outer space, at an altitude of about 300 km. It was planned to eject three Get Away Special satellites (one during the first and two during the second Space Shuttle flight), each containing about 100 lb of the specified hydrazine fuel, plus the required circuitry for tracking and ordinance activation to disperse its contents.

#### 10.4.3 Atmospheric Decay of Hydrazine

The kinetics and reaction products of autoxidation of hydrazine in the vapor phase were already discussed in Section 3.1.1.1. Under laboratory conditions, it is frequently difficult to simulate unconfined free atmosphere conditions and eliminate the wall effects of the reaction vessels used in the apparatus. Available literature attempts to review the significance of laboratory study results for actual unconfined environmental conditions. Ideally, real-life environmental atmospheric decay studies should be conducted in a large outdoor volume, and remote sensing with a LIDAR (Section 3.6.11.2) would greatly facilitate analysis of the environmental pollutant. Fortunately, hydrazines are not very persistent in the atmosphere. At the same time, this makes it difficult to catch and hold them for environmental decay kinetic studies long enough because they may be all gone by natural decay before the experiment is

over. Experimental methods for the study of atmospheric decay of hydrazine vapors in the dark are described in [22].

## 11 Hydrazine Fuel Mixtures

Among the main disadvantages of hydrazine as a fuel are its high freezing point and the difficulty in using it as a regenerative coolant in bipropellant rocket engines. Both of these disadvantages can be overcome by mixing hydrazine with other fuels.

Many studies have been conducted on hydrazine fuel mixture formulation [2598]. Hydrazine fuel mixtures could have been discussed in this book either in the chapter on hydrazine or in the chapter on the fuel that is used as an additive to hydrazine. It was decided to discuss hydrazine fuel mixtures at the end of the chapters on fuels, e.g.,  $\text{NH}_3$ , UDMH, or EDH, that are used as additives, because those are the more volatile or more toxic components ( $\text{NH}_3$ , UDMH) that would determine the handling and safety properties of such mixtures more than hydrazine that accepted these additives.

Hydrazine/ammonia fuel mixtures were already described in the chapter on ammonia. The hydrazine fuel mixtures with UDMH, Aerozine-50 will be discussed in the chapter on dimethylhydrazines, and MHF-3 will be discussed in the chapter on methylhydrazine.

### 11.1 H-70 Hydrazine/Water Fuel Mixture

The physical properties of hydrazine/water mixtures were already described previously in Sections 2.1.2.1 and 2.1.9.4. The most important hydrazine/water mixture is H-70, which is used as a gas generant in gas generators for EPUs in fighter aircraft such as the F-16. This fuel mixture contains 70%  $\text{N}_2\text{H}_4$ , which is just a little more hydrazine than hydrazine hydrate, which contains 64%  $\text{N}_2\text{H}_4$ . Theoretically H-70 could be made from HH100 hydrazine hydrate by adding just a little anhydrous hydrazine to bump the hydrazine content from 64 up to 70%. However, commercial HH100 contains too much carbon dioxide and other contaminants such that the fuel mixture made by this method would not meet criteria of MIL-PRF-87930B. Therefore, H-70 must be made by diluting monopropellant-grade anhydrous hydrazine with carbon-dioxide-free deoxygenated distilled water.

### 11.2 Military Specifications for H-70

The Military Specification for H-70 is essentially a watered-down version of MIL-PRF-26536F with the changed requirements of 69–70%  $\text{N}_2\text{H}_4$  and 30% minimum  $\text{H}_2\text{O}$ . The specification contains several analysis methods for assay and contaminants in H-70.

### 11.3 Other Hydrazine Fuel Mixtures

Numerous other fuels have been tested as additives to hydrazine to improve its freezing point and cooling capability behavior [2598]: Hydrazine and aniline form a eutectic mixture, which freezes at 237 K (−36 °C) and has a composition of 17.3 mass-% hydrazine and 82.7 mass-% aniline. This composition possesses highly improved hypergolic ignition properties with mixed acid and with fuming nitric acid, as compared to aniline alone.

### 11.4 Gelled Hydrazine Fuels

#### 11.4.1 Selection of Gelling Agents

Gelling agents that were proven to work for MMH or UDMH will not necessarily work for hydrazine. The polarity and solvent behavior of hydrazine as a solvent is quite different from that of the alkylhydrazines. One gelling agent evaluated for hydrazine and alkylhydrazines is polyacrylamide [2599].

Gelling agents of polyacrylic acids containing repeating units of

are those sold under the tradenames Carbopol 934, Carbopol 940, and Carbopol 941 with molecular masses of 1–3 million, which are trademarks of the Goodrich Company. Up to 33 mass-% aluminum powder could be suspended in a hydrazine gel with 2% Carbopol 940 [2600].

#### 11.4.2 Gelled Metallized Hydrazine Fuels

An experimental program to prepare thixotropic gels of hydrazine, MMH, and UDMH at ambient temperature included particulate, chemical, and synthetic gellant materials [2601]. Gelation of the liquid fuels was achieved with gellant concentrations as low as 1 mass-% in some cases. Hydrazine hydrate could be gelled by gelling agents like pectin, polyacrylamide (PAA,  $M > 5 \times 10^6$ ), polyvinyl alcohol, carboxymethylcellulose (CMC), hydroxyethyl cellulose (HEC), and ASPAA-II, whereas MMH was successfully gelled by low- and high-substitution methylcellulose, HEC, hydroxypropyl methylcellulose (HPMC), and AS-PAA-II in required concentrations. The gels of UDMH have been prepared using gellants such as Cab-O-Sil, PAA, low- and high-substitution methylcellulose, and HEC. Subsequently, MMH gelled fuel systems with HPMC and ASPAA-II gellants were chosen for metallization due to their low gellant concentration requirement and better gel quality. Metallized heterogeneous gels using up to 40 mass-% of Al or Mg metal powders showed a reduction in required gellant concentration with increasing metallization. The storage studies on gelled systems without metals over a period of 3 months showed good gel stability, but the metallized gels had segregated. A storage life of 3 months is insufficient for most applications. A suggestion

that aged, settled gels could be re-homogenized by stirring is totally unrealistic for most applications.

#### 11.4.2.1 Alumizine

A complete characterization of two specific gel systems, beryllium in anhydrous hydrazine and aluminum in anhydrous hydrazine gelled with Carbopol 940, revealed that the preparation of these gel system is very difficult. The gel characterization included rheology, thermal stability, mechanical stability, storage properties, shock sensitivity, and contamination properties.

There are more detailed studies on metallized MHF-3 fuels because they have a lower freezing point than those with hydrazine (see *Encyclopedia of Liquid Fuels*, chapter “Methylhydrazine”).

#### 11.4.2.2 Gelled Hydrazine/Metal Hydride Fuels

Adding aluminum hydride to hydrazine creates a more energetic fuel, which when burned in a rocket chamber with NTO will allow a specific impulse that is 39% greater than that of a hydrazine fuel in which the aluminum hydride is omitted. Major difficulties have been encountered with hydrazine fuels containing aluminum hydride due to the evolution of gas during storage. The evolution of gas is apparently caused by the catalytic decomposition of hydrazine on the surface of the aluminum hydride. To overcome the gas evolution problem, it has been proposed to coat the aluminum hydride with various polymeric coating materials. The gelation of hydrazine containing aluminum hydride has been accomplished using several different commercially available gelling agents. However, most of these gelling agents are not satisfactory because they are easily shear thinned and have a long recovery time. A poly [(alkyl or aryl)-(alkyl or aryl) semicarbazide] copolymer coating on aluminum hydride eliminated the gas evolution problem and at the same time caused gelling of the hydrazine fuel to eliminate the need for additional gelling agents [2602].

#### 11.4.2.3 Gelled Hydrazinium Nitrate/Hydrazine Solutions

Solutions of HN in hydrazine or hydrazine hydrate can be used as energetic monopropellants or liquid explosives. Many gelling agents that work with plain hydrazine will fail to create a gel in hydrazine or hydrazine hydrate in the presence of hydrazinium ions from hydrazinium salts. A solution (slurry) of 60% HN in 40% hydrazine hydrate was gelled with 0.8% partially hydrolyzed polyacrylamide, 1.2% guar gum, and 1.8% sodium carboxymethyl cellulose [2603].

### 11.5 Hydrazine Fuel Mixtures as Energy Carriers

Hydrazine hydrate and hydrazine mixtures have been tested as fuels in air/hydrazine fuel cells and in internal combustion engines intended for automotive propulsion.

A ternary fuel consisting of 64% hydrazine, 10% ammonia, and 26% water was tested in a stationary internal combustion engine and proposed as an environmentally friendly (no CO<sub>2</sub> emissions) alternative to gasoline [2604].
